Abstract—Small-scale fading and propagation delay have been characterized for the 2.4 GHz band in a specific conference room with 802.11 coverage problems and a more typical conference room for comparison. The measurements were executed with a virtual SIMO (Single-Input Multiple-Output) system. The implications on the 802.11 performance have been investigated in terms of received signal strength and intersymbol interference. A higher reverberation time was found in the room with coverage problems, which causes a higher chance of intersymbol interference.

I. INTRODUCTION

In literature, delay properties of indoor wireless channels are mainly investigated for typical environments like offices, factories and colleges [1]. This paper is focused on a specific conference room where repeated coverage problems were reported with an 802.11 conference system. This system has a SISO (Single-Input Single-Output) configuration. According to the manufacturer, these problems only occur in this conference room and cannot be attributed to interference sources after spectral analysis.

In this paper, small-scale fading and propagation delay are characterized for the 2.4 GHz band in the conference room with coverage problems (room A) and in another more typical conference room (room B) for comparison. Implications on the performance of 802.11 systems are investigated in terms of reduced signal strength and intersymbol interference (ISI).

II. MEASUREMENTS

Measurements were executed in room A and B with a virtual SIMO (Single-Input Multiple-Output) system. In this setup, the Tx and Rx antenna, both broadband omnidirectional Electro-Metrics antennas of type EM-6116, were connected to a Rohde & Schwarz ZVR vector network analyzer, which measured the scattering parameter S_{21} as a function of the frequency. A coaxial cable with two amplifiers was used to realize the required Tx-Rx separation. The position of the Rx antenna, attached to a frame of BiSlides, was controlled by a laptop.

The measurements were done in the frequency range 2.5 – 3 GHz, which is out of the 2.4 GHz band to exclude interference sources. In room A, 801 frequency points were used, which allows to resolve power delay profiles for delays up to 1.6 μ s (greater than the 802.11 Guard Interval of 800 ns

[2]). This delay corresponds to a path length of about 475 m. A 23×23 Rx array was used, with a separation of 1.5 cm. This corresponds to 3.6 samples per $\lambda/2$ (where λ is the wavelength), and a total array dimension of 3λ . In room B, the following settings were used: 401 frequency points, a 4×4 Rx array with a separation of 4 cm.

In room A, the following positions of Tx and the Rx array were considered (Fig. 1): Tx at position 1 (usual position of the access point during meetings) and Rx at position 2 (chairman's seat on the conference table) (case 1a) (and vice versa (case 1b)), and Tx at position 1 and Rx at position 3 (other seat at the conference table) (case 2a) (and vice versa (case 2b)). At position 1, the height of the antenna (Tx or Rx) was always 1.8 m, while at positions 2 and 3, the antenna height was always 1.2 m. The distance between Tx and Rx for case 1a-b is 8.9 m, for case 2a-b 6.9 m.

Fig. 1. Plan of conference room A. The conference table is indicated by (3). Measurements were executed at Tx/Rx positions 1 – 3. The wall behind position 2 (indicated as (1)) and the two dividing walls (indicated as (2)) contain about 30 metal HVAC plates. The wall at the other side (indicated as (4)) consists of windows only.

The wall of room A behind position 2 (indicated as (1) in Fig. 1) and the two dividing walls (indicated as (2) in Fig. 1) contain about 30 metal HVAC (Heating, Ventilation, and Air Conditioning) plates (dimension 1 m by 1.5 m). The wall at the other side (indicated as (4) in Fig. 1) consists of windows only. The ceiling, which looks like a part of an ellipsoid, contains a metal wire mesh, with a minimal separation of about 1 cm. The dimensions of the room are 12 m $\times$ 53 m and the ceiling has a maximal height of 13 m.

Conference room B is cylinder-shaped with about 30 m diameter and a height of about 7 m. Tx was positioned 1 m

from the wall at a height of 2 m and the Rx array was set at two different positions (case 3a-b) near the middle of the room, at a height of 1.2 m. The Tx-Rx separation is 18.4 m for case 3a and 15.3 m for case 3b. For all measurements (rooms A and B), there was a line-of-sight condition.

III. SMALL-SCALE FADING

The performance of the wireless system can be reduced by small-scale fading. The ratio between P_R [dBm] (the power leaving the Rx terminals) and P_T [dBm] (the power entering the Tx terminals) is given by the measured scattering parameter S_{21} : $P_R - P_T = 20 \log(|S_{21}|)$, where $|\cdot|$ is the absolute value.

An estimation of the minimum required $|S_{21}|^2$ value can be made as follows. Taking into account the gains of the measurement Rx and Tx antenna (1 dBi), the Rx gain of a realistic wireless system (4 dBi), and a maximum allowed EIRP (Equivalent Isotropically Radiated Power) of 20 dBm, we estimate the received power of the wireless system as $|S_{21}|^2 + 22$ dBm. The sensitivity of the 802.11n reference receiver is -64 dBm for 65 Mbps (Packet Error Rate < 10%) [2]. Hence, we estimate that there is good coverage when $|S_{21}|^2 > -86$ dB.

The cumulative distribution function (CDF) of the measured $|S_{21}|^2$ samples is determined for the different cases (Fig. 2). Each CDF is based on all Rx positions (of the array) and all frequency points. The probability that $|S_{21}|^2 < -86$ dB is of the order of $10^{-5} - 10^{-4}$ for cases 1a-b and 2a-b, and of the order of $10^{-4} - 10^{-3}$ for case 3a-b. These are low probabilities, but the position of deep fades (drops of $|S_{21}|^2$) can be easily influenced by little changes in the environment (e.g. people).

Fig. 2. CDF of $|S_{21}|^2$ for cases 1a-b and 2a-b (room A) and case 3a-b (room B).

To compare the degree of small-scale fading in the CDFs of $|S_{21}|^2$ for the different cases, we should take into account that for higher Tx-Rx separation, the $|S_{21}|^2$ values are lower. Therefore, we plot the CDF of $|S_{21}|^2 - (|S_{21}|^2)_{av}$ (see Fig. 3), where $(|S_{21}|^2)_{av}$ is the average of the (linear-scaled) $|S_{21}|^2$ samples. Note that for low probability, the CDFs in Fig. 2 and 3 are less accurate due to the finite number of samples. The degree of small-scale fading is higher for case 1a than for case 2a (horizontal shift of the CDF tail of 8 dB at

a probability of 10^{-3} , see Fig. 3) and is also higher for case 1b than for case 2b (horizontal shift of the CDF tail of 4 dB at a probability of 10^{-3}). The degree of small-scale fading of cases 3a-b seems to lie between case 1a and case 2a. The difference in degree of small-scale fading between case 1a-b (position 2 involved) and case 2a-b (position 3 involved) can be explained by the fact that position 2 is closer to and more surrounded by metal HVAC plates than position 3. Note that in room A more coverage problems were reported at position 2 than at other seats at the conference table (e.g. position 3). This is in agreement with the higher degree of small-scale fading for cases 1a-b (position 2 involved) than for cases 2a-b (position 3 involved).

Fig. 3. CDF of $|S_{21}|^2 - (|S_{21}|^2)_{av}$ for cases 1a-b and 2a-b (room A) and case 3a-b (room B).

IV. DELAY

In this section, the propagation delay is investigated with the focus on intersymbol interference (ISI). We assume a Guard Interval (GI) of 800 ns [3]. Based on the SIMO measurements, Averaged Power Delay Profiles (APDP) were made for all cases [4] (see Fig. 4). The resolution is 2 ns for all APDPs. The diffuse part of the APDP [dB] can be expressed as

$$APDP = C_0 - 10 \log(e)(\tau - \tau_0)/\tau_r, \quad (1)$$

where τ_r is the reverberation time (i.e. time over which the APDP is reduced by the exponential factor e) and τ_0 is the delay of the first arriving path [5]. Thus, by definition, C_0 is the power of the extrapolated diffuse part of the APDP, evaluated at τ_0 . Since for all cases, there is a line-of-sight condition, τ_0 is d/c , where d is the distance between Tx and Rx and c the speed of light. The parameters τ_r and C_0 are determined from the APDPs (Table I). We see that τ_r is a factor 2 higher in room A (134 – 138 ns) than in room B (55 – 59 ns), while C_0 is 5 dB higher in room B than in room A. The higher τ_r in room A can be explained by the vicinity of many metal structures (HVAC plates, wire mesh in the ceiling).

The signal transfer (voltage over Tx terminals to voltage over Rx terminals) has a power reduction of $|S_{21}|^2$, measured at the carrier frequency (assuming that $|S_{21}|^2$ does not vary much over the bandwidth of the signal). Paths which arrive

Fig. 4. Averaged power delay profiles for cases 1a-b and 2a-b (room A) and case 3a-b (room B).

TABLE I

PARAMETERS OF THE DIFFUSE PART OF THE APDPs FOR THE DIFFERENT CASES: REVERBERATION TIME τ_r AND C_0 . POWER REDUCTION P_{GI} (DUE TO PATHS ARRIVING AT RX LATER THAN $GI + \tau_0$) (THEORETICAL ESTIMATION) IS COMPARED WITH $(|S_{21}|^2)_{av}$.

	τ_r [ns]	C_0 [dB]	P_{GI} [dB]	$(S_{21} ^2)_{av}$ [dB]	$P_{GI} - (S_{21} ^2)_{av}$ [dB]
case 1a	135	-83.0	-56.7	-45.0	-11.7
case 1b	134	-82.2	-56.0	-43.9	-12.1
case 2a	138	-82.6	-55.4	-45.1	-10.3
case 2b	137	-81.5	-54.8	-43.0	-11.8
case 3a	58.5	-77.0	-91.6	-53.7	-37.9
case 3b	54.9	-77.0	-96.0	-52.8	-43.2

at Rx with a delay higher than $\tau_0 + GI$ can cause ISI. The contribution of these paths can be worst-case estimated theoretically by a power reduction P_{GI} of:

$$P_{GI} = 4 \exp(-GI/\tau_r) \frac{C_0 M}{\tau_{res}^2} \tau_r^2, \quad (2)$$

where τ_{res} [s] is the resolution of the APDP, and C_0 and P_{GI} are in linear scale. M is a margin due to constructive interference between paths with different angle of arrival. M has been determined experimentally as follows. Based on the power delay profiles of all Rx positions, the maximum power is obtained as a function of the delay (Fig. 5). M is the difference between this maximum power and the averaged power delay profile. In this way, we find that the margin M is 9.5 ± 0.5 dB for all cases. The power reduction P_{GI} should be much lower than $|S_{21}|^2$ to exclude ISI [3]. Based on the experimentally determined parameters τ_r , C_0 and M , we calculate P_{GI} with (2). Here, a resolution τ_{res} of 3.3 ns is considered (see further). These P_{GI} values should be compared with $(|S_{21}|^2)_{av}$: $P_{GI} - (|S_{21}|^2)_{av} = -12.1$ to -10.3 dB for room A and -43.2 to -37.9 dB for room B. This is caused by the higher τ_r (factor 2 higher) for room A. Note that small-scale fading has been cancelled out in $(|S_{21}|^2)_{av}$. If we take into account small-scale fading, fades higher than about 10 dB and 40 dB (relative to $(|S_{21}|^2)_{av}$) can theoretically cause ISI for rooms A and B, respectively. This indicates that there is a greater chance of intersymbol interference in room A than in room B.

Fig. 5. Maximum of all power delay profiles (of all Rx positions) and averaged power delay profile (APDP) for case 1b (room A). The vertical shift corresponds to the margin M : $M = 9.5 \pm 0.5$ dB.

Equation (2) is a theoretical worst-case estimation of P_{GI} . However, it is possible to determine P_{GI} as a function of frequency f per Rx array position fully experimentally. This is done by reconstructing the transfer function (voltage over Tx terminals to voltage over Rx terminals) corresponding to the paths which arrive at Rx with a delay lower than $\tau_0 + GI$. This reconstruction is done from the part of the impulse response (of which the absolute value gives the Power Delay Profiles (PDP)) with a delay $< \tau_0 + GI$. Thus, this transfer function is $S_{21}(f) - S_{21,GI}(f)$ for paths arriving with a delay $< \tau_0 + GI$ at Rx, where $S_{21,GI}(f)$ is the transfer function corresponding to the paths which arrive with a delay $> \tau_0 + GI$ at Rx. P_{GI} is then $|S_{21,GI}(f)|^2$. $|S_{21}(f) - S_{21,GI}(f)|^2$ should be much higher than $|S_{21,GI}(f)|^2$ to exclude ISI.

The reconstruction of the transfer function $S_{21}(f) - S_{21,GI}(f)$ has been done for the frequency range 2.65 GHz - 2.85 GHz. To minimize the influence of the window, used for the Fourier transformation in the calculation of the impulse response, we calculate for each measured frequency point an impulse response to reconstruct the transfer function around that frequency point. These PDPs are based on a lower frequency span (i.e. 300 MHz). Consequently, they have a bit higher resolution (i.e. 3.3 ns), but have the same maximum delay, over which the PDP can be resolved. This maximum delay has to be higher than GI (0.8 μ s). This maximum delay is 1.6 μ s for cases 1a-b and 2a-b, and 0.8 μ s for cases 3a-b. Therefore, we can do the reconstruction only for cases 1a-b and 2a-b.

We investigate for cases 1a and 2a whether $|S_{21}(f) - S_{21,GI}(f)|^2$ can be lower than $|S_{21,GI}(f)|^2$, for the 23×23 Rx positions and all frequency points in the range 2.65 GHz - 2.85 GHz (namely 321 frequency points). In this case, symbol errors due to ISI can be expected. For case 1a, this occurs 7 times (out of 169,809 samples). Here, the minimal (worst) ratio $|S_{21}(f) - S_{21,GI}(f)|^2 - |S_{21,GI}(f)|^2$ is -8.5 dB. This situation is illustrated in Fig. 6, where $|S_{21}(f) - S_{21,GI}(f)|^2$ and $|S_{21,GI}(f)|^2$ are shown (in a small frequency range of 10 MHz). For case 2a, this occurs 8 times. Here, the minimal (worst) ratio $|S_{21}(f) - S_{21,GI}(f)|^2 - |S_{21,GI}(f)|^2$ is even -21.0 dB (Fig. 7). This shows that when (small-scale) fades

are deep enough, the contribution of the paths arriving with a delay $> \tau_0 + GI$ can exceed the contribution of the paths arriving with a delay $< \tau_0 + GI$, which results in ISI. From Figs. 6 and 7, we see that fades of 30-40 dB (compared to $(|S_{21}|^2)_{av}$ level) can cause intersymbol interference. This is in agreement with the theoretical estimation in Table I (most right column, case 1a and 2a), which says that intersymbol interference can occur for fades deeper than about 10 dB.

Fig. 6. Power reduction $|S_{21}(f) - S_{21,GI}(f)|^2$, corresponding to the paths which arrive at Rx with a delay $< \tau_0 + GI$: solid line. Power reduction $|S_{21,GI}(f)|^2$, corresponding to the paths which arrive at Rx with a delay $> GI + \tau_0$: dashed line. This is for **case 1a** (room A). The markers indicate the calculated points.

Fig. 7. Power reduction $|S_{21}(f) - S_{21,GI}(f)|^2$, corresponding to the paths which arrive at Rx with a delay $< \tau_0 + GI$: solid line. Power reduction $|S_{21,GI}(f)|^2$, corresponding to the paths which arrive at Rx with a delay $> GI + \tau_0$: dashed line. This is for **case 2a** (room A). The markers indicate the calculated points.

V. CONCLUSIONS

Small-scale fading and propagation delay have been characterized for the 2.4 GHz band in a specific conference room (room A) with 802.11 coverage problems and a more typical conference room (room B) for comparison. The measurements were executed with a virtual SIMO system. The implications

on the 802.11 performance have been investigated in terms of received signal strength and intersymbol interference.

At the chairman's seat in room A (where most coverage problems were reported), an 8 dB higher degree of small-scale fading was found compared to another seat on the conference table. Power delay profiles revealed that the reverberation time τ_r in room A is a factor 2 higher than in room B. These findings could be explained by the vicinity of many metal structures in room A, especially near the chairman's seat.

We showed that the propagation properties of room A can result in coverage problems due to a reduced received signal strength as well as intersymbol interference. Due to the higher τ_r in room A, intersymbol interference can theoretically occur for (small-scale) fades higher than 10 dB and 40 dB in rooms A and B, respectively.

VI. ACKNOWLEDGMENT

This work was supported by the OMUS (Optimizing Multimedia Service Delivery) project, co-funded by the IBBT (Interdisciplinary institute for BroadBand Technology), a research institute founded by the Flemish Government in 2004, and the involved companies and institutions. W. Joseph is a postdoctoral fellow of the FWO-Flanders.
