CASE REPORT

A case of recurrent non-small-cell lung carcinoma and paraneoplastic Cushing's syndrome

Cushing;
Ectopic ACTH;
Non-small-cell lung
carcinoma

Summary Secretion of ectopic adrenocorticotrophic hormone (ACTH) with consequently Cushing's syndrome is a rare paraneoplastic phenomenon. It has been described in a variety of malignancies, like bronchial carcinoids, small-cell lung carcinoma, thymoma, pancreatic carcinoma and other. In many cases of suspected ectopic ACTH secretion, it is difficult to histologically or cytochemically confirm the diagnosis. We present a 63-year-old woman with a recurrent poorly differentiated squamous cell lung carcinoma with clinical and biochemical features consistent with ectopic Cushing's syndrome. Immunocytochemical staining confirmed the secretion of ACTH by tumour cells.

1. Introduction

“The name of Harvey Cushing (1869–1939) was immortalized in the history of medicine, by his discovery, in 1912, of Cushing's disease, an endocrine syndrome caused by a malfunction of the pituitary gland. This discovery was described in detail in: The Pituitary Body and its Disorders [1].”

Cushing's syndrome is characterized by truncal obesity, a ‘buffalo hump’ and/or ‘moon face’, purplish abdominal striae, ecchymoses and proximal myopathy, accompanied by non-specific symptoms like edema, hypertension, fatigability and weakness, hirsutism, hyperpigmentation and diabetes. The syndrome can be ACTH-independent due to autonomous glucocorticoid-secreting adrenocortical adenomas or carcinomas. However, in most cases Cushing's syndrome is ACTH-dependent. The aetiology is bilateral adrenal hyperplasia due to hypersecretion of pituitary ACTH or ectopic production of ACTH by a non-pituitary cause like malignancy, respectively called Cushing's disease and

Cushing's syndrome. Numerous tumours have been reported to secrete ACTH, like bronchial carcinoids, thymoma, pancreatic malignancy and small-cell lung carcinomas (SCLC).

We present a patient with a previous history of non-small-cell lung carcinoma (NSCLC), typical features consistent with Cushing's syndrome and mediastinal lymphadenopathy on computerized tomography (CT).

2. Case report

In March 2005, a 63-year-old woman presented in our hospital with progressive dyspnea. She had a history of previous poorly differentiated squamous cell lung carcinoma of the lower right lobe in June 2001. For this, she had a lobectomy in another hospital with pathological tumour-staging pT1N0M0. After the operation she had gradually gained 50 kg of weight, which she ascribed to cessation of smoking. In January 2005, the general practitioner diagnosed her with hypertension and diabetes.

At presentation, physical findings showed a Cushingoid appearance, with a moon face, buffalo hump and centripetal obesity. There were no signs of hirsutism or hyperpigmentation, nor were there abdominal striae or ecchymoses. There was pitting edema of the legs and some tachypnea. Blood pressure was elevated (RR 175/75 mmHg). Her medication included a potassium sparing diuretic combined with a loop diuretic to control hypertension and edema, a biguanide to control glucose-levels and inhalation-corticosteroids.

Initial laboratory evaluation revealed a severe hypokalemia (K^+ 1.8 mmol/l, Ref. range 3.5–5.0) with normal sodium, magnesium and calcium-levels and a normal renal function. Arterial blood gas analysis revealed a metabolic alkalosis with hypoxemia (pH 7.60; BE 17.1; HCO_3^- 41.1 mmol/l (Ref. range 22–29), pO_2 53.6 mmHg (7.15 kPa) and pCO_2 40.0 mmHg (5.33 kPa)).

She was treated with intravenous and oral potassium chloride and supplemental oxygen. The diuretics were temporarily discontinued, however a potassium-sparing diuretic had to be re-started because of increasing edema of the legs. Hypertension was treated by an angiotensin I-blocker, utilizing its potassium-sparing quality.

Further investigations revealed high 09:00 h plasma cortisol (1.58 μ mol/l, Ref. range 0.18–0.72) with loss of diurnal variation (midnight plasma cortisol 1.43 μ mol/l, Ref. range <0.21). Urinary free cortisol was also elevated (12.16 μ mol/24 h, Ref. range 0.03–0.28 μ mol/24 h), and so were the

plasma ACTH-level (223 ng/l, Ref. range 7–50) and plasma renin activity level (6.70 ng/ml/h, Ref. range 0.8–5.5). Serum cortisol failed to suppress following 1 mg dexamethasone overnight (09:00 h cortisol 1.55 μ mol/l, Ref. range <0.14). Magnetic resonance imaging (MRI) did not reveal adenomas of the pituitary gland, suggesting that our patient had ectopic ACTH syndrome (EAS).

To identify the source of the ectopic ACTH-production while considering her previous history of a lung carcinoma, a thoracic CT-scan was made, which showed mediastinal lymphadenopathy. On the abdominal CT-scan, there were no signs of adrenal hyperplasia or adenoma. Subsequently bronchoscopy was performed which did not reveal abnormalities. Curved linear endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) was performed to biopsy the enlarged lymph nodes and cytological examination demonstrated poorly differentiated squamous cell carcinoma. Assuming the prior resected tumour in the lower right lobe to be the primary tumour, this lymph node can be regarded as N3. Immuno-cytochemical staining of this specimen was positive for the neuroendocrine marker CD56 and for ACTH, suggesting paraneoplastic Cushing's syndrome (Fig. 1).

The patient was treated with ketoconazole (400 mg three times daily) and plasma cortisol levels decreased, as did the potassium-suppletion needed. She developed bacteraemia with *Staphylococcus Aureus*-species, originating from a contaminated intravenous catheter. After two weeks of antibiotic treatment, induction-chemotherapy for TxN3M0 NSCLC was administered (Vinorelbine 25 mg/m² and Cisplatin 80 mg/m²). Ten days later, she developed bilateral pulmonary embolisms for which low molecular weight heparin (LMWH) was started. The patient deceased 18 days after onset of chemotherapy. Post-mortem autopsy revealed multiple bilateral pulmonary embolisms as direct cause of death.

3. Discussion

In ACTH-dependent Cushing's syndrome 20–25% of cases are caused by ectopic ACTH syndrome (EAS). It is well known that several lung tumours like bronchial carcinoids and small cell lung carcinoma are associated with EAS in approximately 1–5% of cases [2,3]. In recent literature, bronchial carcinoids seem to be the predominant cause of EAS, while the incidence of SCLC associated with EAS seems to decrease [9]. A possible explanation for this might be the declining incidence of SCLC, apart

from the fact that SCLC associated with Cushing's syndrome will be less reported due to the known association.

A non-small cell lung carcinoma causing ACTH-dependent Cushing's syndrome has been seldom reported. In 1975, Imura et al. [4] reported three patients with adenocarcinoma of the lung, three patients with undifferentiated lung carcinoma and one patient with a squamous cell carcinoma of the lung, which were all accompanied by ectopic ACTH secretion. However, these patients had no clinical signs of Cushing's syndrome. Since then, only four case-reports of NSCLC associated with EAS have been published [5–8]. In two of these cases, the diagnosis EAS could not be confirmed by tumour cell staining for ACTH or ACTH-precursors [7,8]. In the present case, however, the cytological material obtained stains for ACTH. Revision of the initial pathology specimens of 2001 showed no ACTH-expression by tumour cells at that time. It is known that tumour-relapses can show further de-differentiation while developing neuro-endocrine features such as ACTH-secretion. For squamous cell carcinoma this is seldom seen.

All variables strongly support paraneoplastic type of Cushing's syndrome in this patient rather than a pituitary one. The existence of a lung carcinoma with positive immunocytochemical staining for ACTH is the most important observation. Furthermore, a severe hypokalemic alkalosis is common in EAS and is found in 71–100% of cases of ectopic ACTH secretion, but only in 10% of cases of pituitary ACTH syndrome [9]. Serum ACTH-levels were markedly elevated and levels above 200 $\mu\text{mol/l}$, as in our patient, are rare in pituitary Cushing's syndrome. To exclude other causes of Cushing's syndrome, MRI of the pituitary gland was performed. Although no micro-adenoma was observed, it is reported that about 50% of pituitary micro-adenomas cannot be detected by MRI [21]. Unfortunately, obduction of the brain was not permitted by the relatives of the deceased. Inferior petrosal sinus ACTH sampling may be important in distinguishing between pituitary and ectopic ACTH-production [10]. In our case however, this sampling was not performed because delay in inhibiting cortisol-production with ketoconazole would negatively influence the primary outcome. Furthermore, delay could be regarded unethical because of the finding of ACTH-positive cells by cytochemical staining.

The ultimate manner to control paraneoplastic ACTH syndrome is dependent on successful treatment of the primary tumour. There are several reports about the complications of chemotherapy in patients with ectopic ACTH-production. The com-

plications reported are mostly related to severe infections and gastrointestinal bleeding or ulceration [10,11]. A small study of Dimopoulos et al. [12] reported nine out of 11 patients with SCLC and paraneoplastic Cushing's syndrome to decess within two weeks after onset of chemotherapy. Shepherd et al. [11] found that ectopic ACTH-production is associated with a low response to chemotherapy, short survival and a high rate of complication.

Ketoconazole is used in the treatment of Cushing's syndrome, as it primarily inhibits CYP11B1 (11- β -hydroxylase) but also CYP11A1 (desmolase, cholesterol side-chain cleavage enzyme) in the adrenals. 11- β -hydroxylase is the enzyme responsible for the hydroxylation of 11-deoxycortisol to cortisol while desmolase converts cholesterol to δ -5-pregnenolone [13–15]. Only a few reports about the usefulness of glucocorticoid biosynthesis inhibitors in ectopic ACTH syndrome are published, and they report controversial results [16–20]. In the study of Winkist et al., the conclusions were that ketoconazole did not prolong survival, but it did provide a palliative hormonal response in two third of patients. In our patient, after administration of high doses of ketoconazole (400 mg three times daily), serum cortisol-levels and subsequently hypokalemia were finally controlled.

The present patient died of recurrent bilateral pulmonary thrombo-embolisms despite treatment with LMWH. Both active malignancy and Cushing's syndrome are associated with a hypercoagulable state because of an increase in plasma clotting factors like Factor VIII and von Willebrand factor complex, and to an impairment of fibrinolytic capacity [22,23]. This could explain why our patient suffered recurrent pulmonary embolisms despite adequate anticoagulant treatment.

In conclusion, we believe this patient presented with a Cushing's syndrome paraneoplastic to a poorly differentiated squamous cell carcinoma of the lung. Although uncommon, ectopic Cushing's syndrome can also be found in NSCLC, and is associated with a worse prognosis due to severe complications.
