Assessing the potential impacts of climate change on traditional landscapes and their heritage values on the local level: case studies in the Dender basin in Flanders, Belgium

The Landscape Atlas of Flanders describes the traditional relic landscapes in Flanders (Belgium), characterized by important heritage values and more specifically by natural-scientific, historical, socio-cultural and aesthetic values. These heritage landscapes constitute a considerable part of the common cultural heritage and are therefore managed by specific landscape management plans. However, these plans do not address climate change vulnerability and adaptation, while this is considered as an important driving force of landscape change. This change may impact on the unaffected traditional character of heritage landscapes and cause these valuable landscapes to deteriorate. In this study, we assess and map the potential overall impact of climate change on two relic landscapes in Flanders and map possible adaption measures on a detailed level to allow insertion in the landscape management plans. Detailed synthesis vulnerability and adaptation maps are elaborated in a

GIS, based on the results of impact- and model studies. The vulnerability maps indicate that both case studies are sensitive to climate change. In particular, forest desiccation, wind throw, crop deterioration, soil erosion and flooding might affect the landscape quality and threaten the natural-scientific, historical and aesthetic heritage values of the landscapes. In order to preserve these heritage values, the adaptation maps present possible adaptation measures, which are sustainable and non-destructive with respect to the landscape quality. Although adaptation will cause change as well, it offers more chances to preserve the heritage values of the landscapes. To be effective, detailed climate change vulnerability and adaptation maps should be included in the binding landscape management plans.

1 INTRODUCTION

Like in most parts of the world, the climate in Belgium is changing. Measurements of the Royal Meteorological Institute show an increase in the mean temperature of 2°C between 1833 and 2009 (Brouyaux et al., 2009). The Intergovernmental Panel on Climate Change (IPCC, IVth Assessment Report, 2007) predicts a further increase in the mean temperature between 1.8 and 4.0°C by 2100 compared to 1990. Measurements of the total yearly precipitation in Belgium have also shown a rising trend of +7% since 1910. Between 1833 and 2009, the mean winter precipitation rose by 15% (Brouyaux et al., 2009). Winter precipitation is predicted to increase 3 to 50% by 2100, while in summer a decrease of up to 50% is estimated (Ntegeka et al., 2008). Moreover, evaporation will increase with higher temperatures (Boukhris et al., 2008) and the water availability of soils will decrease, especially in summer (Manabe et al., 2004). Finally, storms will become more frequent and intense due to global warming (Frei et al., 2006). All these changes can be considered as

primary effects of climate change. Secondary effects are flooding and drought, which in turn induce tertiary effects such as impacts on nature and agriculture, for example the extinction of species as a result of drought. The combination of these effects can cause drastic changes to landscapes, which are seen as quaternary effects (Pedroli et al., 2010).

So far, most studies on the impact of climate change have been sector-oriented (e.g. the EEA Report (2008), the Stern Review (2007)) and have focused on above-country scale (Rannow et al., 2010). The impact of climate change on the local level and landscapes, however, has rarely been analysed. In particular, intact traditional, cultural landscapes deserve special attention as these are part of our common heritage, like stated in the World Heritage Convention (1972). According to this convention, ‘cultural landscapes’ are “at the interface between nature and culture, tangible and intangible heritage, biological and cultural diversity - they represent a closely woven net of relationships, the essence of culture and people’s identity” (Rössler, 2006). Often, the management approach of such landscapes is oriented towards preventing changes, like climate change. However, it would be more beneficial to tackle inevitable changes, and thus reinforce the resilience of the system (Bieling et al., 2011; Lemieux et al., 2011). Bieling et al. (2011) describe resilience as “the ability to deal with disturbances or change without altering the essential characteristics of the system in question”. This approach focuses on how to dynamically adapt to processes of breakdown and renewal, rather than on conservation.

This paper follows the resilience approach and presents an integrated assessment of the potential impact of climate change and the possible adaptation measures in two specific case studies in Flanders. In particular, two traditional landscape relics, characterized by considerable heritage values and differing in landscape type, were selected. Traditional landscapes contribute to the cultural heritage value of a place as they are the combined result of the natural capacities of an area and the human land occupation throughout history before

the end of the 18th century (Antrop, 2003). The relics of Flanders' traditional landscapes are mapped in the Landscape Atlas, based on four heritage values: the natural-scientific, historical, socio-cultural and aesthetic value. Each value is estimated by a set of concise criteria: coherence (the strength of the relations between the composing elements of a landscape or ensemble), legibility (the degree to which parts of a landscape or the whole landscape structure can be recognized and understood) and soundness (degree of maintenance and care of the landscape site or element). Based on this methodology, relic zones and anchor places were identified (Antrop, 2003). Anchor places are small ensembles that consist of different features related by a unique historical development, which form almost intact landscape entities (Van Eetvelde and Antrop, 2005). Figure 1 provides an overview of the anchor places in Flanders. These anchor places represent the most valuable landscapes of Flanders concerning the cultural heritage, and constitute a considerable part of the remaining common heritage. Therefore, they need special care and attention and an integrated landscape management (Van Eetvelde et al., 2010). This is achieved by the implementation of a new legislation by which anchor places can be designated as 'heritage landscapes'. Following this procedure each heritage landscape is attributed a landscape management plan and management commission, including local stakeholders (Antrop and Van Eetvelde, 2007). However, these plans, and spatial planning in general, are missing detailed vulnerability and adaptation maps to limit the potential effects of climate change. To fill this gap, the threats and risks that climate change presents for landscapes should be assessed using detailed local vulnerability maps in order to outline adaptation plans and preserve the heritage values of the landscapes in the anchor places from deterioration.

In this study, we took up this challenge for two anchor places in Flanders. The first case is situated in the hilly east of the Dender basin; the second is located in the Dender valley (Figure 1). The aim of the study consists of identifying which threats of climate change the

landscapes in both case studies are exposed to, based on the available knowledge from peer reviewed and ‘grey’ literature, output from model studies and expert judgement. So far, research about the potential effects of climate change in Belgium has been conducted by different institutions, though mostly focussing on one specific aspect of climate change (e.g. soil erosion, flooding etc., see Section 2). In our study, we attempt to synthesize this information for the two case studies, giving an overview of the potential risks threatening their landscapes as a result of climate change. Therefore, the knowledge obtained from former impact studies is translated into detailed vulnerability maps, locating the risks and threats. Furthermore, possible adaptation measures are determined and translated into corresponding adaptation maps. The maps are produced using GIS-analysis, a method recognized to have a large potential for vulnerability and adaptation assessment (Kasperson and Kasperson, 2001).

2 BACKGROUND: PREDICTED EFFECTS OF CLIMATE CHANGE AND POSSIBLE ADAPTATION MEASURES IN FLANDERS

In support of the vulnerability and adaptation maps we provide an overview of the predicted effects of climate change in Flanders, which could have an impact on landscape, and summarize a number of possible adaptation measures.

2.1 Forests

Higher evaporation due to higher temperatures combined with a decrease in summer precipitation (Boukhris et al., 2008) may cause forests to desiccate. Especially forests located on rich soils are vulnerable (Vos et al., 2007). In addition, desiccated trees are more sensitive to forest fires (de Jonge, 2008) and new diseases and pests shifting northwards (De Groof et al., 2006). As a consequence of more frequent and more intense storms, weakened forests

will also become more vulnerable to wind throw (Schlyter et al., 2006). Consequently, a more effective forest management is required. This includes maximizing ecological diversity, e.g. by introducing new tree species to face the new conditions (Dolman et al., 2000; Metzger et al., 2008), replacing coniferous forests by deciduous forests as these are less prone to forest fire (Veeneklaas, 2008) and strengthening the forest structure by connecting different forests (Noss, 2001).

2.2 Surface water

Increasing winter precipitation associated with climate change will lead to higher peak flows of rivers. During storms, this will increase the flood risk (Dolman et al., 2000), especially in rivers of which the active floodplain has been strongly reduced as a result of flood levee constructions such as dikes (Pedroli and Harms, 2002). Several measures can counter this by increasing the water storage capacity: creating more space for rivers by restoring their natural hydrodynamic function (Pedroli et al., 2002; Vos and Kuiters, 2007), broadening and/or deepening ditches, safeguarding valleys from new buildings (de Jonge, 2008), constructing water retention reservoirs, etc. (Dolman et al., 2000).

In summer, drought will become a danger as well: decreases up to 40% in low flow are expected in Flanders by 2100 (Boukhris et al., 2008). This will cause pesticides, nitrates and phosphates to be less diluted, increasing the risk of toxic effects and eutrophication (Vos et al., 2007). A number of measures for reducing flood risks may also resolve the drought problem, assuring a more constant groundwater level (Vos and Kuiters, 2007) and minimum flow in dry periods (EEA, 2007). However, vigilance about drought issues is recommended because specific drought response is slower than adaptation related to floods. A possible explanation is that floods are often perceived as more threatening and sudden than droughts,

which evolve more slowly and have more indirect consequences (Huntjens et al., 2010). Milligan (2004) even states that “droughts and heat waves are the hidden disaster of Europe”.

2.3 Agriculture

First, the predicted increase in the mean temperature and CO₂-level will improve photosynthesis and respiration, possibly leading to overgrowing vegetation on grasslands (Hughes, 2000), but also resulting in higher crop yields in temperate regions (Olesen and Bindi, 2002; Reidsma et al., 2009). As a consequence, some land might become available for other crops (Rounsevell et al., 2005) such as poplar or willow plantations to produce bio-energy (Ragauskas et al., 2006; Tuck et al., 2006; Rounsevell and Reay, 2009). Second, yields and crop quality are threatened by new pests and diseases shifting northwards (Olesen and Greysen, 1993; Jones et al., 2005; Maracchi et al., 2005). A possible adaptation measure is stimulating natural enemies of the pests in the environment by creating an appropriate habitat for these species. This can be achieved outside croplands by preserving or extending plot edge vegetation such as tree lines or hedgerows. Similarly, borders of wild flowers and herbs can be created around croplands (flowery field edges) (Vos and Kuiters, 2007). More drastic adaptation measures consist of changing crop species (Audsley et al., 2006) or adopting a new land allocation or farming system (Bindi and Olesen, 2011). Third, more frequent and intense storms will increase soil erosion, causing fertile soils to deteriorate (De Groof et al., 2006). Adaptation can be achieved by applying conservation tillage or laying out buffering grass strips (Toy et al., 2002; Spaan et al., 2010). The most efficient manner to reduce soil erosion, however, is reforestation. From this point of view, poplar or willow plantations for bio-energy production can be a valuable solution. Moreover, Veeneklaas (2008) stresses that bio-energy plantations might also be the most profitable alternative in

flood-prone areas because willows and poplars tolerate frequently flooded or saturated soils (Kuzovkina and Quigley, 2005).

2.4 Recreation

Climate change will create new opportunities for recreation since higher temperatures may increase the number of day trips and short holidays (Dolman et al., 2000). Richardson and Loomis (2004) found that, depending on the climate scenario, recreational visits may increase from 9.9 to 13.6% in 2020. Especially areas abounding in water and cool forests might become more popular. To meet this growing demand it may be useful to expand recreational parks where possible (Dolman et al., 2000). Climate change also threatens recreational activities, especially water related ones. Higher temperatures can stimulate toxic algae in pools and lakes to grow more easily, potentially endangering swimmers. Therefore, a rigorous control of the water quality and announcing a swimming prohibition when necessary will be required. Finally, the growing risk of forest fires might occasionally necessitate closing recreational forests for visitors (de Jonge, 2008).

3 STUDY AREA: DENDER BASIN

The research area is situated in the Flemish part of the Dender basin (Figure 1). The Dender is a 65 km long river, formed by the confluence of the Eastern and Western Dender in the city of Ath, (Wallonia) that discharges in the Scheldt near the city of Dendermonde (Flanders). As the Dender is mainly fed by precipitation, long periods of intense rainfall can turn the river into a turbulent stream. Consequently, floods are not exceptional in the valley (Figure 2).

Within the river basin two cases were selected. The first area is the anchor place ‘Vrijthoutbos-Moretteberg’, situated outside the Dender valley in Asse (Figure 1) and characterized by a hilly, open, rural landscape, alternating with large forest parcels. The well

drained ridges, located on fertile loamy soils, are used as cropland, whereas the valleys on wet, loamy and sandy loam soils are occupied by forests and grasslands. The second case is the anchor place, named ‘Dender valley between Idegem and Ninove and the Geitebos’ and situated in the valley between the cities of Ninove and Geraardsbergen (Figure 1). In this valley, most wet clay, loamy or sandy loam soils are used for grasslands or poplar plantations. In combination with the numerous poplar rows, a specific, rather closed landscape is formed. Outside the valley wide croplands on fertile, well drained sandy loam soils create a more open landscape.

4 METHOD AND MATERIALS

The analysis was executed in two steps; the calculation process is illustrated in Figure 3. For each study area we generated a vulnerability map and a corresponding adaptation map in ArcGis 9.3. Data sources used to compile the maps are listed in Table 1.

Table 1 Data sources.

4.1 GIS compilation of vulnerability maps

As we are focussing on the landscape-scale, only the effects with a direct impact on this level were included in the vulnerability map. Effects on smaller scales, like for instance on particular species or specific buildings are therefore not included in this study. Furthermore, only the types of vulnerability with a spatial dimension could be represented on the map, which for example excludes health effects, air quality effects etc. In accordance with the results of former impact studies (see Section 2), we identified four types of vulnerability, which are most likely to occur in the case studies (Figure 3A): the vulnerability of forests to desiccation, the vulnerability of forests to wind throw, the vulnerability to soil erosion and the

vulnerability to floods (only occurring in the valley). The four types of vulnerability were combined into a synthesis vulnerability map.

The time horizon for the vulnerability assessment was set at 100 years because the flood maps for the severe climate scenario, created by the Flanders Hydraulics Research and used in this study, are calculated for floods with a recurrence period of 100 years. The severe climate scenario was chosen because adaptation against floods occurring each 100 years will also protect against floods with shorter recurrences (moderate and limited climate scenarios).

In this section, we describe the method for creating the four separate vulnerability layers, using the vulnerability of forests to desiccation as an example. The three other layers were created similarly and will only be described briefly. The supporting tables and matrices are included in the Appendix.

4.1.1 Data selection and reclassification

The susceptibility of forests to desiccation depends on the vulnerability of the ecosystem and the soil type (see Section 2). Consequently, the input data for the analysis consist of the ecosystem desiccation map and the soil map (Figure 3A). First, forests were extracted from the current land cover as the analysis only applies to forests. Second, the ecosystem vulnerability map (Table 1), based on the characteristics and biological value of biotopes,

Figure 3 Flowchart summarizing the methods for creating (1) the vulnerability maps and (2) the adaptation maps. Gray shapes represent original key data sources (maps), white shapes are layers that have been created from the key data. Rectangles in dotted lines symbolize adaptation measures, while full line rectangles represent the policy domains to which the adaptation measures belong. Finally, shapes in dotted lines reflect layers that are also adaptation measures. Arrows between layers symbolize a selection of particular data from a previous layer, unless mentioned otherwise. ‘Stretched’ refers to the reorganization of a map to present the information by a gradual colour scale.

was used to pinpoint the ecosystems most at risk. Finally, the soil map was integrated into the GIS to identify the vulnerable soil types. Subsequently, each layer was converted from vector into raster data to allow a reclassification according to the degree of vulnerability, in which the most vulnerable areas receive the highest scores. As the layers were summed up and both study areas needed to be comparable, we reclassified all layers in the same manner: ‘value 0’ for the least vulnerable category, ‘value 4’ for the most vulnerable category. However, the number of categories differed for each layer, in some cases leading to decimal class limits, which the *Reclassify wizard* in ArcGis 9.3 does not support. Therefore, all values were multiplied by a factor 100, so that all layers were reclassified between ‘value 0’ and ‘value 400’. The ecosystem vulnerability map and the soil map were reclassified using the categories as shown in Appendix, Table 3a&b. For example, as Vos et al. (2007) suggest that forests on rich soils are more vulnerable to desiccation, clay and loam soils were attributed a score of 400, while sand soils were rated lower.

4.1.2 Calculation of the vulnerability map

Second, the reclassified layers were added up to visualize the vulnerability of forests to desiccation as follows:

$$\text{Vulnerability of forests to desiccation} = \text{Reclassified ecosystem vulnerability map} + \text{Reclassified soil map}$$

The vulnerability of forests for wind throw was obtained similarly (Figure 3A and Appendix Table 4). Schlyter et al. (2006) suggest that the degree to which forests are weakened by desiccation contribute to the susceptibility of forests to wind throw. In addition, the altitude and topography also influence wind throw. In areas characterized by a hilly topography, forests situated on ridges catch more wind than trees located in depressions (Finnigan and

Brunet, 1995). Therefore, the vulnerability layer of forests to desiccation and the 5m-resolution digital terrain model (DTM) were used to calculate the vulnerability of forests to wind throw (Figure 3A). The forest vulnerability map to desiccation was reclassified so that the forests most vulnerable to desiccation were attributed the highest value (Appendix Table 4a). The DTM was reclassified as follows: the higher the altitude, the higher the score because forests situated on ridges are more prone to wind throw (Appendix Table 4b).

To determine the vulnerability to soil erosion and flooding, the potential soil erosion map and the flood maps of the Dender were consulted. The flood maps are available for three potential climate scenarios (severe, moderate and limited), based on hydrodynamic models of the Flanders Hydraulics Research. To produce the vulnerability map, we used the severe scenario flood map to visualize the potential worst case scenario. The values of both maps were stretched between 0 and 400 to assure compatibility with the other vulnerability layers.

Finally, the four vulnerability layers (desiccation, wind throw, soil erosion and flooding) were jointly presented in a synthesis vulnerability map.

4.2 GIS compilation of adaptation maps

The potential effects of climate change are shown on the vulnerability maps. In response to these threats, we produced corresponding adaptation maps, subdivided in four groups of measures: forest management, water management, agricultural management and recreational management. Each group consists of different measures which are visualized in the adaptation map. From all possible adaptation measures reported in earlier research, those offering a long term and sustainable solution without significantly affecting the landscape quality and/or those which fit into the original traditional landscape were chosen. Pests can, for example, be controlled by using pesticides or by establishing flowery field edges. However, pesticides are not sustainable for the environment. Moreover, new plot edge

vegetation will ‘restore’ the traditional landscape and increase its heritage value, as originally field edge vegetation used to be widespread in the case studies. Therefore, we chose the establishment of flowery field edges and plot edge vegetation as a solution for controlling pests.

4.2.1 Forest management

Two measures concerning forest management were applied: active management and conversion of coniferous forest into deciduous forest. Active forest management is crucial for the most vulnerable forests. Therefore, the top 30% of the forests most susceptible to desiccation and the forests highly vulnerable to wind throw were selected from the vulnerability map (Figure 3B). On the adaptation map, these were subsequently shown as forests, needing active monitoring and management to prevent degradation.

To visualize the second forest measure, all coniferous forests were selected from the land cover map and added to the adaptation map as ‘Conversion of conifers to deciduous forests’.

4.2.2 Water management

Water management is only relevant in the second study area. To reduce the flood risk, two major actions were considered (Figure 3B): the construction of a water retention basin and the widening and/or deepening of the ditches, which can store large volumes of water during storms. We consulted the Dender Basin Management Plan to locate the water retention reservoir. To illustrate the second measure, all ditches were extracted from the land cover map and represented by arrows on the adaptation map.

4.2.3 *Agricultural management*

The agricultural management consists of three major adaptation measures: the reduction of soil erosion, the management of redundant or vulnerable farmland and the control of pests inside and outside cropland.

Bio-energy plantations can be an alternative to farmland that has become redundant because of the higher crop yields or agriculturally unproductive as a result of soil erosion or frequent flooding. In order to determine the fields most suitable for bio-energy plantations, we used a Multi Criteria Evaluation. The following variables were considered (Figure 3B): land cover, soil erosion rate, soil type and occurrence of floods.

First, the land use map indicates where new plantations are possible: farmland and abandoned parcels overgrown with shrubs are, for example, preferred above residential areas. Therefore, the land cover map was reclassified (Appendix Table 5a), giving the most suitable land cover categories the highest scores. Second, areas vulnerable to soil erosion are more appropriate to reforest because tree plantations can reduce soil erosion. Consequently, the soil erosion map was reclassified, attributing the highest score to the most erosion-prone areas (Appendix Table 5b). Third, the performance of poplars and willows is maximized on wet loam or sandy loam soils (Hughes et al., 2000; Amlin and Rood, 2002). The soil map was reclassified accordingly (Appendix Table 5c). Finally, areas which are predicted to flood frequently are more suitable for bio-energy plantations as in the long term this might be the most profitable alternative function for these zones (Veeneklaas, 2008). In the reclassification of the flood map, the areas with the largest and most frequent floods were given the highest score (Appendix Table 5d).

Next, each variable was attributed a weight, using an Analytic Hierarchy Process (Saaty, 1980) (Appendix Table 6), in which the importance of a variable compared to all other variables is expressed by a score (2 by 2 comparisons). Scores are given according to the

scale proposed by Saaty (1980, p246). If variable A (e.g. land cover) is more important than variable B (e.g. soil erosion rate), this relationship is given a score of 3 to 9, depending on how much more important it is. If variable A is less important than variable B the score will be 1/3 to 1/9. The weights are then calculated by normalizing the scores of the matrix by dividing each score by the sum of the variable's column. Finally, the weight of the variable is equal to the sum of the normalized values. Variations in the scores of the variables will only cause subtle changes in the weights calculated based upon these scores and consequently have a minor impact on the results as, although scores can vary between 3 and 9 or between 1/3 and 1/9, the direction of a relationship can never be reversed (e.g. vary between 3 and 1/3). In addition, the normalization of the scores reduces the differences. In our calculations (Appendix Table 6), soil erosion and flood risk were considered to be the most decisive variables (total weight of 0.64) because these are the driving forces for cultivating bio-energy plantations. Land cover and soil type have weights of 0.08 and 0.28. The four weighted layers were added using Spatial Analyst's Raster Calculator, resulting in a suitability map for bio-energy plantations:

$$\text{Suitability map for bio-energy plantations} = 0.08 * \text{Reclassified land cover map} + 0.28 * \text{Reclassified soil map} + 0.64 * \text{Reclassified soil erosion map (and Reclassified flood map)}$$

The suitability map represents the suitability of a parcel for cultivating poplars or willows: a value close to 0 means that the parcel is unsuitable; parcels with values close to 400 are very suitable.

Because reforestation must be well-considered with respect to the historical background of the landscape, two additional conditions were considered. First, new poplar or willow plantations must preferably be planted on parcels that have been forested before. Therefore,

the map of de Ferraris, illustrating the landscape at the end of the 18th century, was consulted. Second, the plantations need to be close to existing forests to assure connectivity and prevent a scattered plantations pattern. From all suitable parcels only those indicated as forest on the historical map or adjacent to existing forests were considered for bio-energy plantations and were added to the adaptation map.

Besides reforestation, soil erosion can also be controlled by applying conservation tillage or by establishing buffering strips of grassland on cropland, both measures allowing continuing crop cultivation. A distinction was made between priority and secondary reduction of soil erosion, based on the potential soil erosion map (Figure 3B). The priority group consists of parcels characterized by a high or very high potential erosion rate. Parcels indicated as potentially susceptible to medium soil erosion belong to the second group.

Finally, the agricultural management includes the control of pests inside and outside croplands. On cropland, this can be achieved by establishing flowery field edges, stimulating the presence of the pest's natural enemies. As this is a widespread threat, all cropland fields were extracted from the land use map. Outside cropland, the preservation and reconstruction of plot edge vegetation contributes to the control of pests. To illustrate this measure on the adaptation map, all existing small landscape elements (tree lines, hedgerows etc.) were mapped using orthogonal photographs, dating from 2002-2003. For the reconstruction of plot edge vegetation these photographs were compared to aerial photographs from 1951. All tree lines and hedgerows, that disappeared between 1951 and 2003, were mapped and saved in a new layer (Figure 3B).

4.2.4 Recreational management

Adaptation measures concerning recreational management only apply to the second case, which contains the recreational park of 'De Gavers' situated in a highly flood-prone area. On the adaptation map the entire park is shown, representing the general adaptation measures necessary to preserve the recreational function of the area. Examples are the need for a rigorous control of the water quality in pools and lakes and the closing of the park when the risk of forest fire is too high (Figure 3B).

5 RESULTS

5.1 The case study Asse

5.1.1 Vulnerability

The vulnerability map (Figure 4A) shows that forests, situated on wet valley soils or close to springs, are most vulnerable to desiccation. This is consistent with the results of earlier research by Bresser et al. (2005, pp.65), who concluded that forests on wet soils have difficulty in recovering from desiccation because these tree species require a high water quality. Furthermore, the map indicates that most forests are moderately to highly susceptible to wind throw, which is caused by the open, hilly terrain that freely exposes trees to wind. The vulnerability map also clarifies that soil erosion is widespread in the area; 62% of the croplands, mostly located north of the small stream, are moderately to highly affected (Table 2). Three factors contribute to this problem. First, the topography is characterized by steep slopes, with differences in altitude of more than sixty meters. Second, the majority of the soils are loamy, which are most vulnerable to erosion (De Groof et al., 2006). Finally, most of the land is used as cropland, which significantly increases the risk of soil erosion.

Figure 4 (A) Vulnerability map and (B) Adaptation map of the anchor place Asse.

5.1.2 Adaptation

A comparison between the vulnerability and adaptation map (Figure 4B) indicates that almost half of the forests, mainly situated in the valleys, require an active management to prevent degeneration due to climate change. Four conifer plantations are recommended to be replaced by deciduous trees to reduce the fire risk. As conifers are not indigenous in the area, removing them may partly restore the landscape's original character.

As intensive agriculture is important in the area, measures taken on cropland are widespread. As 79% of the affected croplands belong to the priority group (Table 2), conservation tillage or buffering grassland strips are recommended. Second, all croplands can be protected against new pests by creating flowery field edges (Vos and Kuiters, 2007). Similarly, measures can be taken outside cropland, by preserving or extending tree lines and hedgerows. Finally, the minimum area needed for bio-energy plantations is estimated at approximately five hectares, based on the Flemish reforestation guidelines. The most suitable parcels towards this goal are situated in the east and north of the area.

5.2 The case study Dender valley

5.2.1 Vulnerability

In the Dender valley, only few natural deciduous forests occur, of which most are vulnerable to desiccation, especially those located on wet soils (Figure 5A). The drought resistant poplar plantations, dominating the valley, are less endangered. Furthermore, the forest in the south (Geitebos) is most vulnerable to wind throw. In the valley, forests are more protected against high wind speeds and are consequently less susceptible to wind throw.

In contrast to the first case, soil erosion is a less pronounced problem in the Dender case study, as it only occurs outside the valley and to a smaller extent. However, the issue is not

negligible given that of all croplands, 41% is estimated to experience significant soil erosion (Table 2).

Finally, the vulnerability map indicates that in the severe climate scenario almost the entire valley risks severe flooding. The most vulnerable area is located in the recreational park 'De Gavers'.

5.2.2 *Adaptation*

Figure 5B represents the adaptation map, based on the severe climate scenario and thus consistent with the vulnerability map. The map indicates that most of the forests (nearly 75% (Table 2)) need an active management. In contrast, only one conifer plantation needs to be replaced by deciduous trees.

67% of the croplands affected by soil erosion belong to the priority group (Table 2), of which all are located outside the valley. A more widespread measure is the preservation of plot edge vegetation to control pests because of the numerous tree lines and hedgerows. Analogously, measures concerning grasslands are important as this is the most widespread land cover in the area. Based on the guidelines for reforestation, approximately 15 hectares might be used for bio-energy plantations, mostly situated in the valley.

In contrast to the first case, adaptation measures concerning water management are necessary. A water retention reservoir needs to be constructed on the Molenbeek to safeguard the centre of Zandbergen and the area downstream from flooding. The deepening and/or broadening of ditches may increase the water retention capacity, reducing the flood risk. As at present nearly all parcels are surrounded by ditches and tree lines, this is a widespread adaptation measure.

Figure 5 (A) Vulnerability map and (B) Adaptation map of the anchor place Dender valley.

Finally, it is recommended to adapt the management of the recreational park, including the expansion to meet the growing number of visitors. This is only possible on the northern side of the park, by building a pedestrian bridge over the Dender, which would include the river into the park instead of being a border. Furthermore, in summer, when temperatures are highest, the water quality of the lakes requires a more frequent and stricter control to protect swimmers against diseases caused by toxic algae. Finally, dikes need to protect the area against floods.

Table 2 Calculation of the areas related to different adaptation measures.

	Surface in case study Asse	Surface in case study Dender valley	Proportion in the total surface of the case study	
			Asse	Dender
Forests	1,39 km ²	1,17 km ²	15,8%	9,1%
Most vulnerable forests to be managed actively	0,68 km ²	0,86 km ²	7,7%	6,7%
Proportion of all forests to be managed	48,9%	73,5%		
Cropland	2,27 km ²	2,04 km ²	25,8%	16%
Cropland highly or moderately vulnerable to soil erosion	1,41 km ² (62,1%)	0,84 km ² (41,2%)	0,16%	0,07%
Priority control of soil erosion	1,11 km ²	0,56 km ²	12,6%	4,4%
Proportion of all affected cropland to be controlled in priority	78,7%	66,7%		
Secondary control of soil erosion	0,30 km ²	0,28 km ²	3,4%	2,2%
Proportion of all affected cropland to be controlled secondary	21,3%	33,3%		
Bio-energy plantations	0,08 km ²	0,15 km ²	0,9%	1,2%

5.3 Impact on landscape and its heritage values

The vulnerability maps (Figure 4 and 5, section A) illustrate that a deterioration of forests, grasslands and croplands caused by climate change might affect a landscape as a whole. In particular in our case studies, increased soil erosion, drought and a loss of biodiversity may damage the natural-scientific value of the landscape, while a removal of the traditional plot

edge vegetation can decrease its historical value. Furthermore, the aesthetic value of the landscape is threatened as well. In summary, we can thus not exclude that climate change may have an impact on the landscape quality (Callaghan et al., 2004; McEvoy et al., 2008), in particular in vulnerable, high quality heritage landscapes (Cassar, 2005). As a consequence, a potential loss of the heritage values of such landscapes must be taken into account. Moreover, due to climate change, relic landscapes may become less coherent as the relations between the composing elements of the landscape are weakened. In addition, the different parts of the landscape may become less recognizable and less understandable, which may decrease its legibility. Finally, the landscape's soundness (*sensu* Antrop, 2003) might be affected as well because it might look uncared-for. In the worst case scenario, a loss of heritage values can cause the formerly most valuable landscapes to be downgraded or even to lose their status of cultural heritage, which implies suspension of special care and attention. This can especially become reality if, following the example of the UK (Cassar, 2005) and the Netherlands (de Boer, 2009), the Flemish Agency for Immovable Heritage starts monitoring the quality of the cultural heritage in Belgium on a regular base, including heritage landscapes. Adaptation measures can counter this scenario, although this implies change as well. The adaptation maps (Figure 4 and 5, Section B) suggest that bio-energy plantations might emerge on the grasslands which, in the climate change scenario, would be overgrown with shrubs. Furthermore, the deciduous forests can revive as a result of the introduction of new, more resistant tree species, green deciduous trees may replace the dead conifers and flowery field edges can safeguard the crops on the fields from pests and soil erosion. Although adaptation to climate change will alter the landscape, the overall impact will not be destructive with respect to the coherence, legibility and soundness (*sensu* Antrop, 2003) of the landscape, which is essential to preserve the landscape's heritage values.

6 DISCUSSION

One could wonder if climate change should be considered as a serious problem for landscapes and if efforts should be made to preserve them. Several factors may contribute to this doubt. Climate change studies are often based on assumptions or potential scenarios and are therefore characterized by uncertainty (Metzger et al., 2008), both in time and in magnitude. This may contribute to a ‘wait-and-see attitude’. In addition, a number of changes like increasing drought and erosion only proceed very slowly, making them hardly noticeable (Meyer et al., 2010). Consequently, the need for adaptation is not always clear. However, many studies confirm that climate change will have an effect on soils (Lavee et al., 1998; Nearing et al., 2004), water availability (Manabe et al., 2004; Frei et al., 2006; Otero et al., 2011), river systems (Arora and Boer, 2001; Huntjens et al., 2010), agriculture (Rounsevell and Reay, 2009; Bindi and Olesen, 2011; Lorencová et al., 2013) fauna and flora (Burns et al., 2003; Berry et al., 2006) and on ecosystems in general (Harris et al., 2006; Lemieux et al., 2011). These findings provide strong indications that the landscape as a whole may also be affected by climate change as it integrates all these single aspects into one entity (Thompson et al., 1998; Callaghan et al., 2004; McEvoy et al., 2008).

So far, traditional heritage landscapes have often been forgotten, when it comes to preserving the ‘cultural heritage’ against climate change. ‘Cultural heritage’ is too often reduced to monuments (buildings, bridges, statues etc.), like in the “Atlas of climate change impact on European cultural heritage: scientific analysis and management strategies” (Sabbioni et al., 2010). Traditional landscape relics and landscapes in general are rarely included in climate change vulnerability assessments and thus in policy making, while they are for sure part of the cultural heritage. Awareness should be raised among policy makers about including the landscape aspect when assessing climate change vulnerability and adaptation. If considerable

and expensive efforts are currently made to -investigate how to- protect (architectural) monuments against climate change (e.g. protection against floods, acid rain etc.) throughout Europe (Council of Europe, 1985; Pickard, 2002; Tsakalof et al., 2007; de Ferri et al., 2011), it would make sense to preserve our traditional landscape relics as well.

The results of our study suggest that for preserving the heritage landscapes, it is useful to elaborate and map vulnerability and adaptation assessments. Although adaptation to climate change requires coordination over multiple levels of governance (Jäger and Moll, 2011; Bennett et al., 2012), the local level is most appropriate to create these assessments (Lim et al., 2004) as it is on this level that the consequences of climate change will be felt (Adger, 2001) and adaptation measures may need to be implemented (Huq et al., 2006; Satterthwaite et al., 2007). However, although the need is urgent, taking immediate and drastic adaptation actions in heritage landscapes may not be opportune. Because of the uncertainty, it is difficult to predict which effects will actually occur and how strong their impact will be (Metzger et al., 2008; Rannow et al., 2010). Currently, most heritage landscapes in Flanders do not show clear signs of degradation caused by climate change. Taking drastic adaptation measures now could therefore do more harm than good with respect to the landscape quality. Nevertheless, a number of small and quick measures like establishing flowery field edges to control pests (Vos and Kuiters, 2007) and applying conservation tillage to improve the soil structure and stability (Holland, 2004) can already be executed. In the longer term, if climate change persists, more fundamental adaptation actions may be required, like for instance switching over to bio-energy plantations (Rounsevell and Reay, 2009). In any case, climate change cannot be ignored and adaptation will be required, radical or subtle (King, 2004). Detailed vulnerability assessments and appropriate and well-founded adaptation plans will therefore be indispensable to policy makers (Lim et al., 2004).

In Flanders, the first step to realize this is to include adaptation plans into the landscape management plans of the heritage landscapes. This assures action as these plans are binding upon policy makers. If these adaptation plans are not drawn up, adaptation might become very difficult, slow and inefficient. In addition, outlining a univocal adaptation strategy based on scientific research with clear guidelines for all heritage landscapes provides a solid framework for policy makers and land owners. This also restricts the possibility that land owners start taking adaptation measures at their own initiative, which might result in a wide variety of inefficient and unverifiable actions not geared to one another or in no adaptation at all. The impact on the landscape would in this case be highly unpredictable, uncontrollable and heterogeneous, which would probably undermine the landscape quality.

In Belgium, however, more research on the specific local effects of climate change is required to be able to elaborate such a framework. So far, research related to climate change has mainly focused on mitigation (den Ouden and Vanderstraeten, 2004), but a clear understanding of the specific effects of climate change in Belgium is needed to effectively adapt to it. An integrated assessment is therefore indispensable, including a shift from mitigation to adaptation based, interdisciplinary and multi-scale research. For Flanders, this approach is necessary to create more reliable local vulnerability and adaptation maps, which should first be elaborated for the heritage landscapes as according to Cassar (2005), such landscapes are a valuable and vulnerable part of the common cultural heritage. In the longer term, the methodology can be extended to the whole Flemish region, because heritage landscapes cannot be considered as isolated islands. Mismanagement of adjacent areas could have consequences for these landscapes. Although the methodology used in this study can be

applied to other landscapes/areas, the results might vary depending on the landscape type concerned and the local effects of climate change.

In order to make this system work, considerable efforts are needed to integrate adaptation plans into the spatial planning system in general (Meyer et al., 2010). In Flanders, however, this has not yet been achieved because of the difficulties of translating uncertain scientific climate projections into adaptation plans, which hampers the communication between climate modellers/impact assessors and spatial planners/landscape experts (Rannow et al., 2010). In addition, the political situation in Belgium contributes to the absence of climate change adaptation plans in spatial planning. Since the state reform in the 1970s, spatial planning, landscape protection and management, nature and environment have become the authority of the regions, while climate has remained a federal policy. This does not facilitate policymaking as decisions are taken on different levels, which are not always geared to one another. This divergence leads to unexpected situations, like illustrated by the floods of 2010 (Figure 2). As the Dender is separately managed by the Walloon and Flemish regions, only the Walloon part was dredged in spring 2010. In November 2010, this resulted in major floods in large areas downstream in Flanders, while no floods occurred in Wallonia.

Since recently, efforts have been made to address climate change issues in Belgium. The first initiative has been taken with the formulation of a national climate policy by the National Climate Commission in 2009, though still mainly focussing on mitigation. The Belgian National Climate Change Adaptation Strategy has been published (National Climate Commission, 2010), summarizing the potential threats posed by climate change per sector in Belgium. Moreover, it highlights the need for adaptation and focuses on concrete actions. However, the last step, the formulation of a comprehensive national adaptation plan has not

yet been taken. Meanwhile, the Flemish and Walloon regions have started to establish a Regional Adaptation Plan (National Climate Commission, 2010). Furthermore, a number of research projects, dealing with adaptation to climate change, are currently running or have recently been finished (e.g. ‘Science for Sustainable Development’, the Circle-2 ERA-net (Belgian Federal Science Policy Office), the AGORA Programme (Belgian Federal Science Policy Office and Public Health Department), the interdisciplinary research project CcASPAR (Flemish Agency for Innovation by Science and Technology) (Allaert et al., 2012), and the Interreg Projects SCALDWIN, TIDE and AMICE (National Climate Commission, 2010)).

7 CONCLUSIONS

In Flanders, the Landscape Atlas lists the traditional landscape relics, which can be considered as a valuable part of the cultural heritage, based on their natural-scientific, historical, socio-cultural and aesthetic values. More specifically, these relics are labelled as ‘heritage landscapes’, which are assigned a binding landscape management plan to assure the maintenance of their heritage values. However, these plans do not contain climate change vulnerability assessments nor adaptation plans, while climate change is an important driving force of landscape change. In heritage landscapes, this change may affect the intact traditional character of these landscapes, which may cause a part of our common cultural heritage to deteriorate or even get lost. To moderate this tendency, the potential impacts of climate change and adaptation measures could be assessed and mapped on a detailed level. In this study, we elaborated this idea for two relic landscapes in the Dender basin in Flanders and created vulnerability and adaptation maps in a GIS. The vulnerability maps indicate a considerable susceptibility to climate change in both cases. In the case study of Asse, situated outside the Dender valley, a large part of the deciduous forest is prone to desiccation and

wind throw. Soil erosion seems to be an important threat as well. In the case study located in the Dender valley, almost the entire area is threatened by severe flooding. Furthermore, forest desiccation, wind throw and soil erosion are less pronounced than in the first case study, although these issues cannot be neglected either. These effects might deteriorate the landscape quality in both case studies, threatening the valuable heritage values of these landscapes. In particular, the natural-scientific, historical and aesthetic values might be at risk as a consequence of a decline in legibility, soundness and coherence (*sensu* Antrop, 2003) of these landscape relics. As these effects are probable in all Flemish heritage landscapes, climate change should be considered as a real threat to this part of the common cultural heritage. While immediately taking drastic adaptation measures could be precipitous and unnecessary, we at least recommend to assess the vulnerability of relic landscapes to climate change and to start elaborating adaptation plans and maps on a detailed level to preserve this part of the cultural heritage. To be binding, these maps can be implemented in the landscape management plans of each heritage landscape. Although we only examined relic landscapes, in the longer term it might be advantageous to apply the proposed approach to the whole Flemish region. To be effective, climate change adaptation measures will need to be included into spatial planning instruments in general, while the landscape aspect should be more addressed when assessing climate change vulnerability and adaptation.

APPENDIX: Reclassification and weighting of the thematic layers for the compilation of the vulnerability and adaptation maps.

Table 3 Reclassification of the ecosystem vulnerability map (a) and soil map (b) for the compilation of the vulnerability map of forests to desiccation.

	Original value/description	New value	Vulnerability to desiccation
(a)	1	0	no information available
	2	57	not vulnerable to desiccation
	3	114	almost not vulnerable to desiccation
	4	171	little vulnerable to desiccation
	5	229	moderately vulnerable to desiccation
	6	286	vulnerable to desiccation
	7	343	very vulnerable to desiccation
	8	400	highly vulnerable to desiccation
(b)	peat/artificial	0	not vulnerable to desiccation
	sand/ loamy sand (on ridges)	200	moderately vulnerable to desiccation
	clay/loam/sandy loam (on ridges)	400	highly vulnerable to desiccation

Table 4 Reclassification of the vulnerability map of forests to desiccation (a) and the Digital Terrain Model (b) for the compilation of the vulnerability map of forests to wind throw.

	Original value/description	New value	Vulnerability to desiccation
(a)	0-100	0	almost not vulnerable to wind throw
	100-200	133	moderately vulnerable to wind throw
	200-300	267	vulnerable to wind throw
	300-400	400	highly vulnerable to wind throw
(b)	<20m	0	not vulnerable to wind throw
	20-30m	67	almost not vulnerable to wind throw
	30-40m	133	little vulnerable to wind throw
	40-50m	200	moderately vulnerable to wind throw
	50-60m	267	vulnerable to wind throw
	60-70m	333	very vulnerable to wind throw
	>70m	400	highly vulnerable to wind throw

Table 5 Reclassification of the land cover map (a), soil erosion map (b), soil map (c) and flood map (d) for the determination of the suitability of parcels for bio-energy plantations.

	Original value/description	New value	Suitability for bio-energy plantations
(a)	built areas surface water infrastructure	0	not suitable for bio-energy plantations
	forests	100	little suitable for bio-energy plantations
	cropland	200	moderately suitable for bio-energy plantations
	brushwood	300	suitable for bio-energy plantations
	grassland	400	highly suitable for bio-energy plantations
(b)	no erosion	0	not suitable for bio-energy plantations
	negligible erosion rate	67	almost not suitable for bio-energy plantations
	very low erosion rate	133	little suitable for bio-energy plantations
	low erosion rate	200	moderately suitable for bio-energy plantations
	moderate erosion rate	266	suitable for bio-energy plantations
	high erosion rate	333	very suitable for bio-energy plantations
	very high erosion rate	400	highly suitable for bio-energy plantations
(c)	heavy clay peat artificial terrain	0	not suitable for bio-energy plantations
	dry loamy sand stony loam	57	almost not suitable for bio-energy plantations
	dry clay	114	little suitable for bio-energy plantations
	dry sandy loam	171	moderately suitable for bio-energy plantations
	dry loam	229	suitable for bio-energy plantations
	wet clay	286	very suitable for bio-energy plantations
	wet sandy loam	343	highly suitable for bio-energy plantations

	wet loam	400	most suitable for bio-energy plantations
(d)	10-50cm	0	not suitable for bio-energy plantations
	51-100cm	67	almost not suitable for bio-energy plantations
	101-150cm	133	little suitable for bio-energy plantations
	151-200cm	200	moderately suitable for bio-energy plantations
	201-250cm	266	suitable for bio-energy plantations
	251-300cm	333	very suitable for bio-energy plantations
	>300cm	400	highly suitable for bio-energy plantations

Table 6 Calculation of the weights on the basis of Saaty's matrix for the determination of suitable areas for bio-energy plantations.

	land cover	soil type	soil erosion/floods
land cover	1	1/5	1/7
soil type	5	1	1/3
soil erosion/floods	7	3	1
sum	13	21/5	31/21

	land cover	soil type	soil erosion/floods	weight
land cover	0.08	0.05	0.10	0.08
soil type	0.38	0.24	0.23	0.28
soil erosion/floods	0.54	0.71	0.68	0.64
