ABSTRACT

The combination of runoff-generating areas (saturated soils) and overland flow concentration in features such as drainage ditches makes sloping farmland vulnerable to soil erosion. The establishment of drainage ditches aims at draining the excess of water from the farmland, particularly in areas where soils are saturated in the rainy season. The hydrogeomorphic impacts on the farmland itself and on downstream areas need however also to be studied. Off-site, downstream problems comprise higher peak discharges, leading to gully initiation, an increase in sediment load, and flooding problems. On-site problems such as the development of the drainage ditches into (ephemeral) gullies are much less documented although they may be important, as illustrated in the Lake Tana basin (Ethiopia). The similarities and interactions...
between ephemeral gully channels and drainage ditches have to be considered to better understand all effects of drainage. Drainage ditches are a potential source of conflict between farmers with different interests and power, as well as between up- and downstream users. A case study on drainage ditches on sloping farmlands in the Lake Tana basin showed that 9 out of 10 catchments had drainage densities by ditches ranging from 53 to 510 m ha\(^{-1}\). Drainage ditches were constructed with an average top width of 27 (±9) cm. A significant correlation was found between stone bund density (physical conservation structures) and ditch drainage density (R = -0.72), in line with the Ethiopian government’s ban on drainage ditches in farmlands where stone bunds have been constructed.

**KEY WORDS:** Drainage ditch, cut-off drain, runoff, ephemeral gully, soil saturation, rill, stone bund

**INTRODUCTION**

As population densities are rising, more pressure is put on the land and even steep sloping areas are cultivated (Turkelboom *et al.*, 2008; Smit & Tefera, 2011; Mekuria *et al.*, 2012; Haile & Fetene, 2012). In regions where soils have poor internal drainage and where rainfall depth exceeds evapotranspiration depth during the rainy season, nearly all sloping farmlands require drainage for crop production. Although drainage has a wide range of benefits, in many cases the establishment of drainage ditches is perceived as a major mismanagement of farmland which leads to on-site and off-site land degradation (Smit & Tefera, 2011; Simane *et al.*, 2013; Zhang *et al.*, 2013). The environmental impacts of land surface drainage cannot be simply and clearly stated: for instance Pathak *et al.* (2005) and Turkelboom *et al.* (2008) report that drainage ditches on steep slopes can control gully erosion by diverting the water away from the gully head, whereas other studies point to drainage ditches as a triggers of gullies (Archibold *et al.*, 2003; Ireland *et al.*, 1939; Smit & Tefera, 2011; Zhang *et al*. 2013). Since gully erosion is the worst stage of soil erosion by water and a worldwide problem (Poesen *et al.*, 2003; Valentin *et al.*, 2005), a comprehensive analysis on the hydrological effects of man-made drainage ditches is required.

Here we review the effects of drainage ditches on sloping farmland with a focus on drainage ditch systems as a factor initiating rill and gully erosion. First we consider seasonal soil saturation as a trigger for runoff production (Archibold *et al.*, 2003). As overland flow leads to soil erosion on farmlands and loss of crop yield (Tilahun *et al.*, 2013; Ngatcha *et al.*, 2011; Singh & Agnihotri, 1987), the use of drainage ditches and their positive effects for crop...
production are introduced in the next section. Next, the negative effects of enhanced drainage are presented at different scales. Off-site effects such as gully formation (Burkard & Kostachuk, 1995; Turkelboom et al., 2008) and increased peak discharge (Holden, 2004; Skaggs et al., 1994) are taken into account, followed by the on-site effects (Tebbu et al., 2010; Shiferaw, 2002). Besides these drainage ditches, we discuss thereafter the naturally formed ephemeral gullies which show some similarities with human-made drainage ditches (Bewket & Sterk, 2003; Zhang et al., 2007), and consider the spatial and social dimensions of these effects of drainage ditches. We finish with a brief example of the use of drainage ditches in the Lake Tana basin (Ethiopia) to illustrate the need for further research on the hydrogeomorphic effects of drainage ditches.

METHODS
A critical examination was carried out of 62 scientific (peer-reviewed) journal articles, 3 MSc theses and 13 other publications (governmental reports, Food and Agriculture Organization (FAO) reports, conference proceedings, chapters in books). This review is illustrated through participatory observations on drainage ditches in the Lake Tana basin in Ethiopia, including fieldwork during summer 2013, which consisted of interviewing different stakeholders concerning drainage ditches (government officials, farmers, scientists at the Bahir Dar University), measuring drainage ditch characteristics (top width of drainage ditches, drainage density) and other explanatory factors such as stoniness, soil depth and average slope gradient.

SEASONAL SOIL SATURATION AND RUNOFF
The occurrence of surface runoff has been schematically illustrated by Steenhuis et al. (2009) and Bayabil et al. (2010) who divide basins in the hill slopes and the lower, relatively flatter areas. Precipitation on the hill slopes can partly infiltrate and partly flow downslope as (sub-) surface flow. Areas in the landscape where runon and rain depth are greater than runoff and infiltration become saturated during the rainy season. The differences in flow discharge along the slope are due to differences in slope gradient, concavity of the area, depth to an impermeable layer in the soil (Bayabil et al., 2010), transmissivity (James & Roulet, 2009) and rainfall characteristics (Ziadat & Taimeh, 2013).

Saturation of the soil and jointly its effect on surface runoff is often seasonally bound. Tilahun et al. (2013), Ngatcha et al. (2011) and Singh & Agnihotri (1987) amongst others studied the erosive effects of overland flow due to soil saturation during the rainy season in Ethiopia, Cameroon and India respectively. Concentrated overland flow is the main factor of
gully erosion on cropland (Govers et al., 1990; Auzet et al., 1993). Due to soil saturation, more runoff water is produced that is captured by the drainage ditch system. Higher discharges lead to a larger erosive force of the flows in the downstream gullies (Archibold et al., 2003). Shallow soils, if occurring in the middle and lower parts of the slopes, get saturated more quickly and hence rill and gully initiation is more likely in these areas (Zhang et al., 2007; Steenhuis et al., 2009; Bewket & Sterk, 2003).

DRAINAGE OF SLOPING FARMLAND

The aim of digging drainage ditches on cropland is to reduce the negative effects of excess of water on crops. The primary objective of a drainage system on sloping land is to capture the temporary excess of water and evacuate it downhill. Artificial drainage of the land aims at securing an unsaturated top soil layer and hence (i) reduce the damage from scalding due to the detrimental effect of ponding water in hot areas (Luthin, 1966), (ii) prevent soil compaction as a result of animal trampling on saturated soil, (iii) support crop germination as drained soils are warmer, (iv) prevent subsurface anoxic conditions (waterlogging), (v) enhance the water holding capacity, (vi) increase aeration, (vii) lead to more uniform crop growth, (viii) allow a greater variety of crops, (ix) lead to a deeper root zone, (x) protect plants from disease and (xi) decrease the mechanical power needed for tillage operations. (Luthin, 1966; Robinson, 1990; Spaling and Smit, 1995; Zhang et al., 2013).

In contrast to level areas where drainage ditches mainly aim at lowering the level of the phreatic surface when it comes near or at the surface (Schot et al., 2004; Qureshi et al., 2013), digging ditches to divert runoff water on sloping cropland is a physical soil conservation practice to protect the land from uncontrolled runoff and hence decrease the risk of topsoil and seedling erosion. It is also used to control gully erosion by diverting runoff water away from active gully heads (Pathak et al., 2005; Shiferaw, 2002). Such structures that intercept overland flow and divert it laterally to a supposedly safe and well established drainage channel are called cut-off drain, diversion ditch (Turkelboom et al., 2008), slanted drain or locally in Ethiopia tekebekeb (Shiferaw, 2002) or feses.

In the Roujan basin in France, drainage ditches are 0.7 to 1.2 m wide and 0.8 to 1.4 m deep (Moussa et al., 2002). Million (1996) found in his study in North Shewa highlands in Ethiopia drainage ditches of which the width varied from 30 to 50 cm and depth from 5 to 25 cm. In northern Thailand and Ethiopia, Turkelboom et al. (2008) and Shiferaw (2002) concluded that the widths of the drainage ditches are very variable and mostly determined by
the width of the tillage tool. The depth of the drainage ditch depends often on the soil depth. The gradient of ditches varied considerably from farmer to farmer from 3 to 20% (Million, 1996). Turkelboom et al. (2008) found drainage ditches with gradients of 15-50%. In developing countries, decisions on the dimensions of the ditch construction variables (width, depth, gradient) are based on indigenous knowledge of local conditions and empirical observations. Although some studies mention dimensions of drainage ditches as discussed above, there is a scarcity of literature about the explanatory factors of drainage densities on sloping farmland and about quantities of soil loss associated with the use of drainage ditches.

The main two categories of man-made drainage systems are (i) subsurface drains and (ii) surface drains. Subsurface drainage systems are situated beneath the soil, so the land can be farmed over the drain. Their initial cost is however high (Luthin, 1966). Different surface drainage ditch systems can be distinguished on sloping lands, where they are often ephemeral as they are destroyed during preparatory tillage of the land and shaped again (by hoe or plough) after crop emergence in the period when overland flow starts to occur (Shiferaw, 2002; Million, 1996). The cross-slope ditch system or interception system consists of ditches at the lower end of the slope. Water from the farmland is captured by open collector ditches, running at a slight angle with the contour. The random-ditch system is applied in fields where random depressions exist which are too deep to fill by land smoothing. The ditches will connect these depressions to transport the excess of water downslope. Surface-drainage bedding system is an old drainage practice. Beds are formed in the farmland and separated by parallel open field ditches (Luthin, 1966). These ditches are oriented towards the greatest land slope. Typical examples of such land surface drainage techniques are the Camber bed drainage in for example Ghana (Nyalemegbe et al., 2010) and Ethiopia (Srivastava et al., 1993) or the broad-bed-and furrow (Astatke et al., 2002; Morrison et al., 1990) both of which have been promoted with variable degrees of success (Gebreegziabher et al. 2009). A collector drain at the lower end of the field gathers all the drained water. Parallel-ditch system can be used on flat, poorly drained soils. The land between the parallel ditches is smoothed, so the overland flow encounters no obstruction. For all of the above systems, the cross-sections of the ditches are trapezoidal or V-shaped if they are smaller (Luthin, 1966).

DRAINAGE DITCHES AND DOWNSTREAM HYDROGEO MORPHIC RESPONSES
The use of drainage ditches has an impact on the farmland itself and on the downstream area (Table I). Drainage ditches may cause hydrogeomorphic changes because of their repetitive
and expansive nature (Spaling & Smit, 1995). For example, drainage is frequently associated with a reduction in wetlands or changes in stream discharge (Figure 1). Those changes can be positive as already discussed, or negative: the establishment of drainage ditches is increasingly recognized as a major factor of off-site environmental impact, as it increases sediment load, peak runoff rate and thus increasing flooding problems downstream (Skaggs et al., 1994).

**Gully formation**

The erosive force of the concentrated water flow in the drainage ditches may initiate downslope gully formation and further incision of existing waterways (Ireland et al., 1939; Simane et al., 2013). Farmlands with significant surface run-on may suffer from gully development as observed in the highlands of northern Thailand. Human-made linear landscape features such as diversion ditches or footpaths are most important for runoff concentration, rapid transmission of peak flows to the lower part of the catchment, and hence gully development (Turkelboom et al, 2008). Burkard & Kostachuk (1995) studied gullies in glacial clays in Ontario and observed gully expansion resulting from alteration of surface drainage patterns by agricultural drainage ditches. Archibold et al. (2003) reported similar observations in a catchment in Saskatoon (Canada) where snowmelt is the most prominent source of soil moisture and surface runoff. When the soils are saturated, infiltration capacity is too low and more water is concentrated into the drainage ditch system, which drains into valley bottoms, gullies and first order streams. Lack of cooperation between land users upstream for safe drainage and gully protection may hence lead to severe downstream gully erosion (Smit & Tefera, 2011). Zhang et al. (2013) and Simane et al. (2013) emphasize the importance of a well-thought drainage ditch design in order to benefit from the positive effects resulting from drainage ditches, while reducing the downstream effects. A poorly planned drainage ditch layout leads to enhanced gully erosion downstream (Simane et al., 2013) and causes higher peak runoff discharge, with concomitant losses of soil and nutrients (Zhang et al., 2013).

**Increased peak discharges**

The peak discharge in rivers will be larger where hill slopes have a high drainage density. The drainage density comprises both drainage ditches and natural drainage by gully channels (Holden, 2004; Skaggs et al., 1994). Turkelboom et al. (2008) found that gully development
is closely related to the runoff-generating areas, runoff-concentrating features, and connective elements within the catchment. Drainage ditches increase the runoff connectivity in the catchment (Sidle et al., 2006). The presence of a drainage network is one of the most critical characteristics to identify farmlands that cause off-site problems (Turkelboom et al., 2008). But Trafford (1973) and Thomasson (1975) downplay the effect of drainage ditches on peak discharges: drainage of permeable soils generally results in a lowering of the flow peaks. The concept here is that the drainage ditches lower the temporary water table (induced by seasonal rainfall) and hence increase the temporary storage capacity of the top soil layer (Thomasson, 1975). This results in a larger capacity of the soil to absorb the rain that falls during the beginning of each event.

DRAINAGE DITCHES AND ON-SITE GULLY INITIATION

*Gully formation*

The concentrated water flow in the surface drainage ditch system may also generate on-site effects on the farmland. There is scarcity of literature on this topic although problems of on-site gully initiation are widespread. In western Washington (USA) (Veldhuisen & Russel, 1999) and on the steep and wet highlands of northern Thailand (Turkelboom et al., 2008) drainage ditch failures were observed when ditches got clogged by sediment. Runoff could break through the ditch wall, divert the water out of the drainage ditch and create a rill or a gully. The lack of maintenance of physical structures such as stone bunds (sensu Nyssen et al., 2007) or drainage ditches reduces their effectiveness and even allows concentrated flow which enhances gully development (Tebebu et al., 2010; Shiferaw, 2002). At smallholder level, particularly in complex terrain, creating an effective drainage ditch system requires experience, (indigenous) knowledge of soils, and skills, as too steep ditches enhance incision and gully formation, too shallow ditches create overflow of the ditches and rill formation, and too many ditches are time and space consuming (Smit & Tefera, 2011). Poor design and obstruction of the drains are major causes of gully initiation (Hudec et al., 2005; Alt et al., 2009; Smit & Tefera, 2011).

Holden et al. (2004) studied the impact of peat drainage and concluded that wetland soils suffer from severe degradation due to ditches which can quickly erode deeply. Incised drainage ditches allow higher peak flows and are very dynamic whilst they dissipate little flow energy (Simon & Rinaldi, 2006). Ditch degradation and widening over time are the undesirable effects (Alt et al., 2009; Simon & Rinaldi, 2006) (Figure 2). To avoid ditches
developing into gullies, farmers will yearly change their position (Shiferaw, 2002; Million 1996).

Ireland et al. (1939) characterize gully forms of which some are determined by drainage ditches (Figure 3), particularly, the linear form is common along parcel borders following old or existing drainage ditches, and the parallel system can be formed out of parallel ditches.

*Other on-site effects*

Substantial on-site soil losses to the underground drainage system have also been observed in a catchment in Ullensaker (Norway). This subsurface soil loss was accelerated by the soil saturation at the end of a snowmelt period (Oygarden et al., 1997).

Another possible on-site effect of the construction of drainage ditches is moisture deficit at the end of the rainy season. Hebrard et al. (2006) emphasize the large influence of land management such as drainage ditch networks on soil moisture distribution in a catchment. Nevertheless, literature is very scarce on the specific causal relation between drainage ditches and moisture stress for crops at the end of the rainy season.

**INTERACTIONS AND SIMILARITIES BETWEEN DRAINAGE DITCHES AND EPHEMERAL GULLIES**

Besides man-made drainage ditches, also the effects of natural drainage on hydrogeomorphology can be considered. The hydrological processes associated with ditches were also observed with ephemeral gullies (Poesen & Hooke, 1997), i.e. clearly formed natural waterways mostly reoccurring at the same place (Foster, 1986). Swiechowicz (2011) showed that ephemeral gullies on cultivated areas in Poland are most frequently formed on cultivated slopes in natural drainage lines. Studies conducted in the Mediterranean area (Martinez-Casasnovas et al., 2005), China (Zhang et al., 2007) and in Ethiopia (Bewket & Sterk, 2003; Tebebu et al, 2010) confirm the findings of ephemeral gully (EG) formation on cultivated land, which constitutes the main drainage system. Casali et al. (1999) studied ephemeral gully erosion in Spain by which three main types of EG are distinguished: (i) classical EG, (ii) drainage EG and (iii) discontinuous EG. The drainage EG were formed by flows from drainage ditches in upstream farmlands which erode the cultivated plots downstream. They found that drainage EG were the most active EG and hence eroded the
largest volume of soil. Also in Ethiopia we observed that many ephemeral gullies are fed by runoff water from slanted drainage ditches, although there is a lack of research about this topic. According to Tebebu et al. (2010) and Easton et al. (2010), gullies grow more easily on saturated soils because of positive pore water pressures reducing the shear strength of the soils. Overland flow is the main factor of gully erosion on cropland (Govers et al., 1990; Auzet et al., 1993). Fields in mid-slope positions are more susceptible for rill erosion because of the runoff concentration (Bewket & Sterk, 2003).

When EG are not controlled by tillage operations, they can grow into large gullies (Woodward, 1999; Bennett et al., 2000; Le Roux & Sumner, 2012). Tillage-induced roughness can redirect runoff water from topographically determined directions of flow to tillage lines. This concentrated flow can initiate uncontrolled EG (Takken et al., 2001).

Long-term productivity of the farmland declines because of the repeated removal of top soil by gully erosion followed by the filling operations (Poesen et al., 2006; Yitbarek et al., 2012). Another effect of this process is the gradual lowering of the soil surface (Woodward, 1999; Burkard & Kostachuk, 1995; Valentin et al., 2005). The most documented on-site effects of water erosion and surface runoff include nutrient and soil losses (Poesen & Hooke, 1997; Steegen et al., 2001; Martinez-Casasnovas et al., 2005). All these effects of EG are also applicable to ephemeral drainage ditches that are created yearly in farmers’ fields in different but nearby and parallel positions.

**DRAINAGE AND GULLYING IN RELATION TO SOCIAL AND UPSTREAM-DOWNSTREAM POWER CONFLICTS**

The history of the conflict concerning the effects of man-made hillslope drainage in England has been summarized by Robinson (1990). Severe floods of the Thames (London), Severn (Wales) and other large rivers in England were claimed as being the inevitable result of upstream drainage of farmland. The divided academic opinion about the effects of drainage ditches caused governmental inconstancy. For many years the government has been giving public money to farmers for construction of drainage ditches, whereas they recognized that further research of the hydrological effect of agricultural drainage is required. The study of Bankoff (2013) indicates that this discussion in England is still of interest today. Similarly, drainage of peatlands has worldwide been the subject of conflict between different stakeholders such as nature conservationists, and economists who want to increase farmland...
productivity (FAO, 2012; Koivusalo et al., 2008). Wetland loss by peat drainage has severe consequences for local populations in Africa depending on the source of water and nutrients required for biological productivity. However, decision-makers often perceive wetlands to have little value compared to drained wetlands with more visible and immediate economic benefits (Schuyt, 2005). Also in Scotland, the relationship between peatland soils and man induced drainage has gained attention (Bragg, 2002).

Smit and Tefera (2011) investigated the reason why gully erosion is still present on a hill slope of the Choke Mountain (Ethiopia) despite more than 20 years of soil conservation programs. They concluded that land degradation is not caused by intensive cultivation but by the absence of a coordinated drainage ditch system, that results from the occurring social relations within the community. Larger landowners have a higher status and are put in a favorable position when disputes arise concerning land, irrigation water or other ‘public goods’ distribution. This makes them privileged to construct drainage ditches which may benefit their crop yield but are detrimental for their downslope neighbors. Different interests, different social and topographical positions make it hard to establish a cooperation between land users to stop gully formation.

Farmers try to construct their drainage ditches in such way that they will end up in a stream, forest or a fallow land which can slow down the runoff velocity and trap the transported sediment (Turkelboom et al., 2008). However, Shiferaw (2002) points to the major limitation of drainage ditches in a watershed in East Gojjam (Ethiopia): the ditches are constructed in order to find the best way to drain the excess of water so that they may have to cross croplands belonging to different farmers. These drainage ditches hence form a potential source of conflict between neighboring farmers.

Case studies on drainage ditches (Smit & Tefera, 2011; Shiferaw, 2002; Turkelboom et al., 2008) confirm the theory of Lanckriet et al. (2014) following Blaikie et al. (1994), who state that traditional crop producers in the third world are not in a chronic crisis but the economic impoverishment is caused by human interactions with nature. Despite the land degradation factors often put forward in literature, Lanckriet et al. (2014) emphasise the political mode of production (traditional subsistence, power relations, civil war, post-war) and its related conservation strategies.

AN ILLUSTRATION IN LAKE TANA BASIN IN ETHIOPIA
**Situation**

The Lake Tana basin is situated in the north-western Ethiopian highlands and comprises about 2.5 million people. The basin includes Lake Tana (3041 km²), which is the largest lake in the country and fills a volcano-tectonic depression at 1785 m a.s.l. (Setegn et al., 2010; Poppe et al., 2013). The Lake Tana basin contains lacustrine deposits and the weathering material of basalts both of which support fertile soils (Colot, 2012), particularly Vertisols and Nitisols, as well as Leptosols on the steeper slopes (Miserez, 2013). More than half of the Lake Tana basin is used for agriculture (Setegn et al., 2009). The most applied production system in the Lake Tana basin is the grain-plough complex, with crop production consisting for 70% of cereals (Westphal, 1975).

**Seasonality and rainfed farming**

Rainfall in Lake Tana basin is highly seasonal with more than 70% of the rainfall occurring in the *kremt* season (June-September). The rainfall pattern has an important impact on crop cultivation. The growing season for the Lake Tana region is limited to the duration of the rainy season and a subsequent period with residual moisture (Colot, 2012). Rainfed farming agriculture is dominant in the Lake Tana basin, as it is in most parts of Ethiopia (Colot, 2012; Araya et al., 2012; Hurni et al., 2005).

**Traditional drainage ditches**

Traditional drainage ditches in humid and sub-humid regions of Ethiopia are dug on hillslopes during the rainy season. These ditches are locally known as *feses*. The reasons farmers give for constructing drainage ditches are (i) to avoid soil erosion by runoff water, (ii) to avoid loss of seeds directly after sowing and (iii) to drain accumulating water away from their fields. *Feses* are constructed using the *maresha* ard plough, drawn by a pair of oxen (Gebreegziabher et al., 2009). The gradient, number, spacing, depth and width of the ditches on cultivated land can differ from farmer to farmer, from plot to plot and among crop types. The width of the ditch is chosen by the farmer in function of the depth of the soil, though usually fixed by the width of the ox-plough (Shiferaw, 2002).

We studied ten catchments (0.27-4.21 ha) in the Gumara sub-basin (1279 km²) during the rainy season of 2013; only in one catchment no drainage ditches were present. Drainage densities in the other nine catchments ranged from 53 to 510 m ha⁻¹. The average drainage density by ditches over the nine catchments was 282 (± 155) m ha⁻¹. Farmers constructed
drainage ditches that departed from the contour with angles between 0 and 90° with an average of 45°. Interviewed experienced farmers stated that drainage ditches perpendicular to the contour make no sense as they do not catch much runoff; besides, they cause severe land degradation (deepening and widening of the ditch). The top width of all ditches was on average 27 (± 9) cm (measured directly after establishment), with a minimum of 15 cm and a maximum of 80 cm. After the crops have reached a certain height (decision varies from farmer to farmer), these feses were filled with weeding materials because the functions of the drainage ditches mentioned above were not necessary anymore. A significant correlation was found in the 10 catchments between stone bund density and ditch drainage density \((R = -0.72)\), whereas the latter is also negatively correlated to soil depth (Table II). The negative correlation between stone bund density and drainage density can be explained by the government policy which forbids making feses where stone bunds were constructed at governmental initiative. In this way, the government tries to avoid land degradation by the use of drainage ditches, and hence to support sustainable land management. Nevertheless, drainage ditches still appear in combination with stone bunds (Figure 2) for different reasons mentioned by the farmers: (i) no maintenance of the stone bunds and hence malfunctioning, (ii) the excess of water needs to be drained away and (iii) water overflowing the stone bunds does erode their field. Local courts are very busy during the rainy season resolving conflicts between farmers concerning feses construction draining water to neighboring farmer’s fields. There is only one verdict as the authorities follow the government policy and hence the drainage ditch has to be closed.

**Soil erosion related to drainage ditches**

Farmers alternate the position of the traditional constructed ditches every cropping season in order to avoid their gradual widening and deepening over time (Shiferaw, 2002). Farmers are aware of the fact that drainage ditches transport fertile topsoil from their land downstream. But according to the farmers in Lake Tana basin feses are the best way to avoid soil erosion in the beginning of the rainy season if no other on-site conservation measures like stone bunds are available. As a result of this soil transport, the bottom of the feses frequently reaches down to the bedrock (Figure 4).

Rill erosion and gully formation are the most important processes causing soil loss by water which form a severe threat to the subsistence rainfed agriculture and the national economy of Ethiopia. Thus the lack of knowledge of (i) the process of gully erosion (Poesen et al., 2003;
Tebebu et al., 2010) and (ii) the environmental impacts of artificial drainage (Skaggs et al., 1994) is problematic as it can lead to mismanagement in the basin. This concerns also the livelihoods of tens of millions of people downstream in the lower Nile river basin.

CONCLUSIONS
Sloping farmland is susceptible to erosion induced by high rainfall, seasonal soil saturation and the construction of drainage ditches. Man-made soil drainage has a range of benefits for the farmer’s land, although researchers are still divided about the balance of their positive and negative effects. The similarities and interactions between ephemeral gullies and drainage ditches have to be considered to account for all effects of drainage. The use of drainage ditches has both on-site and off-site impacts. Downstream problems such as increased sediment load, higher peak discharges and gully initiation are well documented. Gully erosion appears as a result of the combination of runoff-generating areas (saturated soils), runoff-concentrating features (drainage ditches) and connectivity in the catchment. But few studies deal with the on-site effects of drainage ditches although problems of soil removal and gully initiation are reported. We recommend further research about the on-site effects of drainage ditches on root depth, moisture conditions and rill and gully formation. The case of the Lake Tana basin illustrates the importance to further study (i) the hydrogeomorphic impacts of drainage ditches and (ii) the similarities with the processes of ephemeral gully erosion. This will enhance better management strategies to reduce the negative impacts on the environment. Finally, drainage ditches are a potential source of conflict between neighboring farmers with different interests and power positions.

ACKNOWLEDGEMENTS
We thank the assistance of the WaSe-Tana project, a cooperation between Ghent, Leuven and Bahir Dar universities, funded by the Belgian development cooperation through VLIR-UOS. We also thank the VLIR-UOS to fund this research through a travel scholarship for E.M. Field discussions with farmers around Wanzaye (Ethiopia) contributed to sharpen our insights in the matter. Constructive comments by Artemi Cerdà and Paolo Billi on an earlier version of this paper are gratefully acknowledged.
