Abstract

Although the Monoamine Oxidase-A (*MAOA*) gene has been linked to spatial learning and memory in animal models, convincing evidence in humans is lacking. Performance on an ecologically-valid, virtual computer-based equivalent of the Morris Water Maze task was compared between 28 healthy males with the low *MAOA* transcriptional activity and 41 healthy age- and IQ-matched males with the high *MAOA* transcriptional activity. The results revealed consistently better performance (reduced heading error, shorter path length, and reduced failed trials) for the high *MAOA* activity individuals relative to the low activity individuals. By comparison, groups did not differ on pre-task variables or strategic measures such as first-move latency. The results provide novel evidence of *MAOA* gene involvement in human spatial navigation using a virtual analogue of the Morris Water Maze task.

Key words: monoamine-oxidase; virtual maze; spatial navigation; spatial memory; learning; gene

1. Introduction

Differences in the variable number of tandem repeats (VNTR) of the Monoamine Oxidase A gene (*MAOA*) have been linked to a variety of psychiatric disorders including anxiety [1, 2], depression [3], or schizophrenia [4]. These disorders are typically associated with cognitive deficits, such as perturbations in spatial learning and memory in anxiety [5] and depression [6]. Therefore, variations in *MAOA* gene expression might also contribute to disease-related cognitive dysfunction such as executive attention [7], working memory [8] or decision-making [9]. This study examines this possibility, specifically in relation to spatial learning and memory.

Basic neuroscience studies support a role of *MAOA* in spatial abilities but have mostly measured *MAO* enzyme activity rather than transcriptional activity of genetic expression. In mice, the *MAOA* inhibitor moclobemide improved spatial performance and novel object exploration [10], whereas pinoline, a *MAOA* and serotonin-uptake inhibitor, reduced the number of arm entries and time spent in the open area of a plus maze [11]. Similarly, inhibition of *MAOA* increased locomotor activity in a water maze task but failed to facilitate spatial learning in adult rats [12]. While these data suggest that *MAOA* influences basic learning and memory processes, parallel evidence in humans remains limited.

To our knowledge, only one previous study in humans assessed the influence of platelet *MAO* on spatial abilities [13]. Their data [13] indicated an inspection time of a perceptual maze that was shorter in high-*MAO* activity males relative to low-*MAO* activity males, but similar in high-*MAO* activity males and low-*MAO* activity females. However, these earlier findings focused on the *MAO* enzymatic activity rather than

MAOA genetic expression, and they were based on a paper-and-pencil maze, a small sample size, and a potential confound of gender. Improving on previous paper-and-pencil based tasks, ecologically-valid, computerized virtual mazes have become available to measure spatial navigation more precisely in humans. These virtual mazes have been shown to be sensitive to exposure to sex steroids [14], age-effects [15], and neurological damage [16].

The *MAOA* gene has a 30 base pair repeat in the promoter region (*MAOA*-LPR) that has been shown to affect transcriptional efficiency *in vitro*. Individuals with the long allele (3.5 repeats and 4 repeats) show greater transcriptional activity (high *MAOA* gene activity) than individuals with the short allele (3 repeats)(low *MAOA* gene activity) [17]. Of note, the *MAOA* gene is located on the X-chromosome. Thus, women have two *MAOA* genes, whereas males have only one copy. While the comparison of high vs. low expressing gene is simple in males (single gene yielding only two genotypes, high vs. low expressing), it becomes more complex in females (two genes yielding 4 possible combinations of the low/high efficiency genes).

The present study evaluates the contribution of high and low monoamine oxidase gene expression by virtue of examining *MAOA*-LPR genotypes in human spatial learning and memory. As a first step, we limited the sample to males to exclude potential confounds of sex [18]. To circumvent issues with age-related cognitive declines in spatial abilities across the life-span [15] as well as age-dependent effects of *MAOA* on spatial performance [19], we specifically focused on young males. With regard to predictions, previous findings have been ambiguous. On the one hand, animal studies measuring enzyme activity suggest that subjects with low *MAOA* activity perform better on learning

and memory tasks than subjects with high *MAOA* activity [10], supported by human genetic expression studies showing better performance in decision-making [9] and higher attainment of educational levels for low-activity individuals [20]. On the other hand, the reverse pattern, a better performance for individuals with the high-activity (long) allele relative to individuals with the low-activity (short) allele has been found in gene expression studies of executive attention [7] and working memory [8]. In addition, molecular work also shows higher transcriptional efficiency in carriers with the high-activity *MAOA* allele [17]. Thus, based on this mixed literature, we sought to compare long and short-allele carriers and expected significant differences between groups on spatial performance parameters on a virtual Morris Water Maze task [14, 21].

2. Materials and Methods

2.1 Experimental subjects

Sixty-nine healthy male adolescents, mostly of Caucasian ethnicity, participated in this experiment. Of these, 28 males (mean age = $19.39 \pm \text{SD } 10.91$; mean IQ: $114.18 \pm \text{SD } 12.46$) were hemizygous for the low (3) activity variant and 41 males (mean age = $16.37 \pm \text{SD } 6.86$; mean IQ: $116.05 \pm \text{SD } 13.18$) were hemizygous for the high (4) activity variant. Both groups were similar in age ($t(41.50)=1.30$, $p=.20$) and IQ ($t(64)=-.58$, $p=.56$), which was measured with the Wechsler abbreviated scale of intelligence [22]. Adult participants and the parents of minors provided written consent, and adolescents provided written assent to participate in protocols approved by the Institutional Review Board of the National Institute of Mental Health (NIMH). Inclusion criteria consisted of an absence of medical or psychiatric problems, as determined by physical examination

and structured psychiatric interviews (Kiddie-Schedule-for-Affective-Disorders–Present-and-Lifetime-version [23]) administered by an experienced clinician (inter-rater reliability $k > .75$), absence of psychotropic medications or drug use and an IQ > 80.

2.2 Materials

A virtual version of the Morris Water Maze [21] was used. It consisted of the display of a square room containing a circular pool of water. Four equally-sized abstract rectangular paintings that were distinguishable by their shape, colour, and placement on the walls surrounding the pool, served as navigational cues to aid orientation. Each of these cues was placed on a different wall of the room and stretched from the ceiling to the pool wall (see Figure 1). Participants navigated in the pool from a first-person perspective and moved around using the ‘up’, ‘left’ and ‘right’ arrow curser keys of the keyboard. Following previous authors’ task-rules [16], to more closely mirror typical rodent behaviour, the ‘back’ arrow key was disabled and participants were told they could not back up. If participants wanted to turn around, they had to spin 180 deg around their left or right axis using the left or right arrow keys.

***** insert Figure 1 about here please *****

Participants completed the experiment on a laptop with a 17 inch monitor in a windowless room of the pediatric clinic of the NIH Clinical Center. The experiment was completed in one session without breaks and lasted about 15 minutes. Following previous

investigators [24], the task consisted of 18 trials, including 2 initial practice trials and 16 experimental trials. On the first practice trial, participants had 30 seconds to explore the room and to learn to navigate comfortably in this environment. No platform was present during this first trial. The platform was introduced on the second practice trial. For this trial, participants were asked to simply “swim” towards the visible platform. Over the next 16 experimental trials, the platform was hidden but always located in the same position. However, the platform location was different from the second visible platform trial and participants had to ‘hunt’ for the platform on the first hidden trial. Participants were dropped in a pseudo-randomised order, which was fixed for all participants, across trials an equal number of times at four different locations on the side of the pool wall. For each trial, the task consisted of “swimming” directly to the hidden platform. Once participants successfully reached the platform, a neutral sound occurred. Participants remained on the platform for 2 seconds before the onset of the next trial. On each trial, participants were given 60 seconds to find the platform, after which the platform became visible and a written message appeared on the screen indicating the visibility of the platform and encouraging participants to move towards it. If such a trial occurred, it was counted as a failed trial.

2.3 Monoamine Oxidase A genotyping

Genomic DNA was prepared from saliva samples collected in the laboratory using Oragene•DNA kits (DNA genotek, Ottawa, Ontario, Canada). The *MAOA*-LPR genotyping was based on Ducci and colleagues [25]. The *MAOA* gene promoter VNTR polymorphism was amplified from 10 ng genomic DNA using the primer sequences:

Forward 5'-(CCC AGG CTG CTC CAG AAA CAT G)-3' and Reverse-5'(GTT CGG GAC CTG GGC AGT TGT G)-3'. Since GC content is high in the VNTR region, Invitrogen's PlatinumTaq and PCR X Enhancer System kits (Invitrogen, Carlsbad, CA) were used for amplification, with 5 μ M of each primer and 25 mM dNTPs in a total reaction volume of 15 μ l. Amplifications were performed on a Perkin-Elmer 9700 thermocycler (Applied Biosystems, Foster City, CA) with one cycle at 96°C for 10 min followed by 35 cycles of 94°C for 15 s, 55°C for 15 s, 72°C for 30 s, and a final 3 min extension at 72°C. The fluorescent dye 6-FAM labeled the forward primer; amplicons were visualized with GeneScan-500 LIZ Size Standard (Applied Biosystems, Foster City, CA) and analyzed on an ABI 3730 capillary sequencer. Allele sizes (allele 2--183 bp; 3--213 bp; allele 3.5--232 bp; allele 4--244 bp; allele 5--272 bp) were determined using GeneMapper v4.0 (Applied Biosystems, Foster City, CA). Genotyping accuracy was determined empirically by duplicate genotyping of 25% of the samples selected randomly. The overall error rate was < 0.005 , and the completion rate was > 0.98 . As *MAOA* is an X linked gene and since our study only included males, genotypes were grouped by relative transcriptional activity of *MAOA* into two categories: high-activity (*MAOA-H*) (4 repeats) versus low-activity (*MAOA-L*)(3 repeats).

2.4 Statistical analysis

A 4 x 2 repeated measures ANOVA was run for each variable using a Block (1-4) by Genetic activity (low vs. high) design on correct-trials only. Five performance variables were used: (1) latency, i.e., the time (sec) spent to reach the platform; (2) path length, i.e.,

the distance (relative to the pool diameter) covered to reach the platform, (3) heading error (in deg), i.e., the angle between optimal heading direction and participant's heading direction; (4) first-move latency, an indicator of how long subjects remained at the wall edge at the beginning of a trial before they started moving towards the platform. In addition, (5) an analysis was run on overall accuracy, i.e., number of failed attempts, in which the latency exceeded 60 sec. To examine learning patterns, the 16 experimental trials were binned into four blocks of four trials each, i.e., block 1: trials 1-4, block 2: trials 5-8, block 3: trials 9-12 and block 4: trials 13-16 (e.g.,[5]). In addition, we assessed pre-navigational motoric and search processes to rule out pre-task group differences. Accordingly, we used a multivariate F-test that included all 5 performance variables to examine the initial 2 trials, the visible platform trial and the first hidden trial in which participants had to search for the platform separately. Although both groups did not differ significantly in age ($p = .20$), because of a lower mean in the high vs. low subjects all analyses were re-run with age as a covariate of no interest to assess impact of this variable. To assess statistical power, measures of effect size (Cohen's d) and post-hoc power (G*Power, [26]) were calculated.

***** insert Figure 2 about here please *****

3. Results

Differences in performance between the 2 genotype groups emerged on several variables.

A significant effect of *path length* indicated a shorter path length for the *MAO-H* vs. *MAO-L* gene variant ($F(1,67) = 4.17, p = .04, d = .51, \text{power} = .74$). A significant main effect of block ($F(3,201) = 7.41, p < .001$) with a significant linear trend ($F(1,67) = 19.54, p < .001$) indicated a learning effect across trials (Figure 2a).

A similar main effect of group was also found on *heading error* showing less heading error for *MAO-H* relative to *MAO-L* individuals ($F(1,67) = 9.91, p = .002, d = .74, \text{power} = .98$)(Figure 2b).

Although there was no significant difference between genotype groups in the *latency* to reach the platform ($F(1,67) = 2.63, p = .11, d = .39$), a significant main effect of block ($F(3,201) = 12.31, p < .001$) indicated learning over the course of the experiment, manifest as a significant linear effect ($F(1,67) = 27.20, p < .001$) (Figure 2c).

The *first-move latency* albeit showing a significant effect of block ($F(3,201) = 10.93, p < .001$) with significant linear trend ($F(1,67) = 7.24, p = .009$) did not show a group difference ($F(1,67) = .44, p = .51$), suggesting that latency to disengage from the arena wall did not contribute to group differences (Figure 2d).

When accuracy, as measured by the amount of *completed trials*, was assessed, *MAO-L* males failed to complete more trials (Mean = 0.30 +/- SEM = 0.06) than *MAO-H* males (Mean = 0.12 +/- SEM = 0.05)($F(1,67) = 5.57, p = .02, d = .54, \text{power} = .85$), showing also a significant main effect of block across groups ($F(3,201) = 2.67, p < .05$).

Importantly, the examination of potential *pre-task* differences revealed no group differences of any of the performance parameters from either the visible platform trial (e.g., latency *MAOA-L*: mean = 13.51 sec +/- SEM = 1.35; latency *MAOA-H*: mean =

13.52 +/- SEM = 1.11) or the first hidden trial (e.g., latency *MAOA*-L: mean = 26.92 +/- SEM 3.72; latency *MAOA*-H: mean = 30.38 +/- SEM 3.07)(all $F(1,67) < 1.10$, all $p > .30$). These data suggest that performance differences were unique to spatial navigation and not associated with motoric ability or ability to locate the platform on the first trial. Despite absence of significant differences in age, analyses were re-run with age as a covariate of no interest. All between-group effects remained significant (path length: $F(1,66) = 4.64$, $p = .035$, heading error: $F(1,66) = 10.31$, $p = .002$ and fail to complete: $F(1,66) = 5.96$, $p = .02$).

4. Discussion

This study provides the first evidence for the involvement of *MAOA* gene expression in human spatial navigation. Males with the low *MAOA* activity allele (*MAO*-L) performed consistently worse on all navigational indices than males with the high-activity allele (*MAO*-H). Critically, potential age-effects or pre-task differences did not influence these findings.

Males with the high *MAOA* transcriptional activity of gene expression performed more efficiently on several spatial performance measures when trying to locate the hidden platform relative to males with the low transcriptional activity. Importantly, no differences were found on the visible platform trial or the first 'hidden' trial, when participants had to locate the platform for the first time and no memory set had been established at that point. Absence of effects on these measures suggests no pre-task differences related to search efficiency or motor ability. Moreover, both groups were well-matched on IQ.

Work on the molecular contribution to spatial learning and memory is still in its infancy. A recent study implicated BDNF, a neurotrophic gene hypothesized to be strongly involved in episodic memory and hippocampal function [27], and with a link to anxiety disorders [28], in spatial orientation [29]. The current findings complement and extend this earlier work to genes involved in deamination of neurotransmitters implicated in prefrontal function such as dopamine, serotonin, and noradrenaline [17]. This is of particular interest as some authors have suggested a prefrontal contribution to spatial navigation [30, 31]. Their hypothesis was supported by fMRI reports on PFC activity during spatial tasks [15, 32]. Interestingly, the high-activity variant of the *MAOA* gene has been associated with increased activity in the medial PFC [33], an area involved in memory with tight connections to the striatum [34]. Moreover, regarding executive processes known to rely on PFC function, individuals with the high-activity variant performed significantly faster than individuals with the low-activity variant on a working memory task [8]. Speculatively, *MAOA* could thus possibly influence spatial cognition indirectly by impacting catecholamine function in PFC and/or striatum. Higher transcription of high-activity *MAOA* gene in males provide larger production of *MAOA* with amplified catecholamine deamination and, in turn, faster clearance of neurotransmitters from the synaptic cleft allowing for a faster turnover of available monoamines. This would be consistent with the idea that individuals with the low-activity variant might have higher levels of homovanillic acid (HVA), a major metabolite of catecholamines in the CNS [25], but show worse performance on executive tasks [7, 8]. However, these findings remain to be clarified at the behavioural level given contrary evidence that individuals with low MAO-A gene expression make better financial

decisions [9] and accomplish higher educational levels given similar IQs [20]. Together with prior work, the current findings imply the involvement of multiple genes in the neurochemistry of spatial cognition and may implicate different neuroanatomical foci. For example, it is conceivable that BDNF might modulate spatial navigation through its action on the hippocampus, whereas *MAOA* might do so at the prefrontal level. Yet, the precise directionality of the findings remains to be confirmed.

In fact, the current data offer exciting new hypotheses to test in animal knock-in/knock-out genetic models using similar navigational tasks to further isolate effects of *MAOA* (and/or BDNF) on spatial abilities. Such research endeavour would further our understanding of the molecular basis of spatial navigation. Indeed, the virtual analogue of the Morris Water Maze is an ideal task for translational work, since it allows to assess the same performance measures across both humans [14] and rodents [35].

Some limitations require discussion. First, we should acknowledge the relatively small sample size, given that this may constrain interpretability of findings in behavioural genetic studies (c.f.[36] for review). However, power analyses of the current study indicated good statistical power to obtain effects of a medium-to-large magnitude. Second, because little is known about sex differences regarding function or distribution of *MAOA*, we limited our analyses to males in order to rule out complex sex by genotype interaction effects and to preserve degrees of freedom. Replication in females is needed to generalize these findings across sex.

4.1 Conclusions

In summary, these novel data provide a window into the neurochemical basis of human spatial navigation and implicate involvement of the *MAOA* gene. Along with other studies, such data are important for guiding behavioural neuroscience research, specifically the neurochemistry of behaviour. Future, translational work might be able to probe more specifically how and where in the brain *MAOA* activity influences cognitive abilities.
