Abstract

The impact of irradiation on host-microbe crosstalk is still underexplored. By use of an *in vitro* oral mucosa model, we show an impact of irradiation on epithelial wound healing depending on the microbial composition and functionality. 454-pyrosequencing analyses pointed to a slight increase in abundance of *Rothia, Granulicatella* and *Gemella* in our model after irradiation. Further research is needed to unravel the effects of irradiation on the oral microbiota and the host-microbe interactions more in detail.

Introduction

Oral mucositis is an important side effect of cancer therapies. In 91% of the patients with head and neck cancer, radiotherapy results in the development of mucositis [1]. The pathobiological process of mucositis can be subdivided in 5 phases: the initiation phase, the primary damage response followed by signal amplification, the ulceration and the healing phase [2,3]. From these, the healing phase is highly variable between patients and is probably the least understood [2,4]. Although differences in treatment schedules, irradiation doses and individual radiation sensitivity may be responsible for the differences in wound healing, the composition of the oral microbiome is also thought to be one of the determining factors. An oral core microbiome has been described for healthy individuals with *Streptococcus* being a predominant genus; yet, genera like *Neisseria, Prevotella, Veillonella* or *Haemophilus* can also become highly abundant. At species level, this interindividual variation is even larger [5]. A recent review describes important shifts in the core oral microbiome due to radiotherapy, with an increased abundance of Gram-negative species and *Lactobacillus spp.* [6]. Irradiation has thus a clear impact on the host and on the oral microbiome, however it is unknown to what extent irradiation affects the host-microbe crosstalk, particularly during the wound healing phase of mucositis. Here, we used an *in vitro* oral mucosa model [7] to study the impact of oral microbes on the dynamics of the wound healing process following irradiation more in detail.

Materials and Methods

Epithelial cell line

TR146 cells, an oral squamous carcinoma cell line derived from a local lymph node metastasis was obtained from Clare Hall Laboratories (Cancer Research UK). The Dulbecco’s modified Eagle’s cell culture Medium (DMEM) (Gibco, Belgium) was supplemented with 10% heat-inactivated fetal bovine serum (Greiner bio-one, Belgium), 22.8 µg/mL penicillin-streptomycin (5000 U/mL; Gibco, Belgium) and 2.5 µg/mL amphotericin B (Bristol-Myers Squibb, Belgium). Cells were cultured at 37°C and 10% CO₂ and regularly controlled to be mycoplasma free (MycAlert Mycoplasma Detection kit; Lonza, USA).

Irradiation

A single 6 MV photon beam was generated using a linear accelerator (SLi-18, Elekta, UK). The 24-well plates were placed on top of a 1.5 cm Perspex (polymethylmethacrylate) plate to compensate for the build-up effect and irradiated from below. The model was irradiated with a total dose of 10 Gy at an instantaneous dose rate of 430 cGy/min.

Oral swab collection

Before sampling, the oral cavity of a healthy volunteer was extensively flushed with drinking water. A sterile cotton swab was used to rub the buccal mucosa 10 times before submersion in 2 mL of synthetic saliva buffer. Briefly, an organic buffer (500 mg/L ureum), an inorganic buffer (2.987 g/L KCl, 2.96 g/L NaH₂PO₄, 0.667 g/L KSCN, 1.9 g/L Na₂SO₄, 0.993 g/L NaCl and 10.8 mM NaOH) and an additive buffer (483 mg/L amylose, 167 mg/L mucin and 50 mg/L uric acid) were autoclaved and mixed (4:3:3) immediately before use. After incubating the oral swabs for 15 min at 37°C, the microbial suspensions were snap frozen in liquid nitrogen and stored at -80°C.
until the experiments were performed. For all experiments, a different oral swab was taken from the same healthy volunteer.

**Oral mucosa model**

To co-culture microbiota and TR146 epithelial cells in non-infectious conditions, we used our recently published oral mucosa model [7]. Briefly, 75 µL of an agar/mucin solution was spotted on the porous membrane (pore size 0.4 µm) of a 24-well plate Transwell® system (Corning Inc., USA) and allowed to solidify for at least 30 min. After thawing at room temperature, 20 µL of the microbial samples (~3.2 log/filter) were brought on top of the agar/mucin layer. In the basal compartment, a confluent layer of TR146 cells was generated by seeding 300 000 TR146 cells into a well after labelling with DiI cell labelling solution (Life technologies Europe, Belgium). Cells were allowed to attach and grow for 3 days prior to wounding.

**Wound healing assay**

TR146 monolayers were scratched using a sterile plastic pipette tip. Floating cells were removed by replacing the medium with fresh serum-free, antibiotics-free DMEM. Filters containing the microbiota and the agar/mucin layer were placed on top of the wounded cells prior to irradiation. By means of an automated fluorescence microscope (Zeiss Axiovert 200M), pictures of 4 selected points along the wounds in each well were taken immediately after irradiation (0 h) and 24 h after incubation at 37°C and 5% CO₂. Migration of the cells into the wounded area in the presence and absence of oral microbiota was assessed by comparing the micrographs after 0 and 24 h (Figures 1A and 2A). The relative surface (%) of the wound was determined by dividing the wound surface after 24 h by the wound surface at time 0. For this we made use of a custom-made macro in ImageJ [7]. For each well, the mean value of the wound surface was calculated (n=1) and used for further analysis. In total, 5 independent experiments were performed, each with 2 to 4 wells per condition.

**Microbial enumeration**

To enumerate the microbiota at the start of the experiment, 10-fold dilutions of the oral swab suspension were prepared in sterile PBS and plated on BHI agar plates (Sigma, Belgium) using the microdilution plating technique. After 24 h of co-culture, microbiota in the apical compartment were suspended in 200 µL of sterile PBS before plating 10-fold dilutions as described above.

**454 pyrosequencing**

DNA extraction and 454 pyrosequencing analysis of the apical compartment was performed as described earlier [7]. On average, 12 907 number of reads were generated by pyrosequencing for each sample. After processing the results, operational taxonomic units were classified using the RDP database.

**Statistics**

Statistical analyses were performed with SPSS statistics 22. After normality check with the Shapiro-Wilk assay, an ANOVA, Student’s T, Kruskal Wallis or Mann Whitney-U test was used. Bonferroni correction was performed to correct for multiple comparisons.

All other techniques used for this study are described in detail in De Ryck et al. [7].

**Results and Discussion**

In patients suffering from oral mucositis, the healing phase spontaneously starts 2-3 weeks after completion of radiotherapy. Signals originating from the extracellular matrix promote wound healing by stimulating migration, proliferation and differentiation of the epithelium [2]. We previously showed our in vitro oral mucosa model to be useful for the study of effects of oral microbiota on the wound healing capacity of different oral-derived cell lines [7]. In non-irradiated conditions, epithelial recovery was significantly reduced with 12-16% in the presence of microbiota (Figures 1B and 2B, 0GY; P<0.001). After irradiation however, our experimental data could be categorized in 2 different sets.

In 3 of the 5 independent experiments (set 1) the inhibitory effect of the microbiota on wound healing was more pronounced after irradiation as compared to the non-irradiated condition (Figure 1B, 10GY; P<0.001). In contrast, no effect of the microbiota after irradiation could be noticed in the other 2 independent experiments (set 2; Figure 2B, 10GY; P=1). Interestingly, plate counts revealed a lower number of microbiota in set 2 after 24 h of co-culture compared to set 1 (P=0.053). We hypothesized that this might be the result of a difference in microbial load and/or composition in the oral cavity of the healthy volunteer at the time of sampling. While the difference in microbial concentrations between the 2 experimental datasets was not influenced by irradiation (Table 1; P=0.979; P=0.800), our data suggest that microbial growth is an important determining factor for the wound healing process after irradiation.

Irradiation has previously been shown to prolong the lag phase for foodborne pathogens delaying the stationary phase [8]. As a consequence, microbial metabolites might be present at concentrations that are too low to have an effect on the epithelial cells. A microbial metabolite that was present in our in vitro model was D-lactic acid [7]. Here we show that oral microbiota increase the levels of D-lactic acid after 24 h in both datasets (Figures 1C and 2C; set1: p<0.001 and set2: p=0.167 and P=0.445), but that irradiation did not have an effect on this increase (P=0.308; P=1). Therefore, D-lactic acid present in the co-culture medium could not explain the difference in effect on wound healing of both sets. Furthermore, the epithelial wound healing was not affected in presence of exogenous D-lactic acid up to 5000 µg/mL (data not shown).
irradiation, this was only observed in 50% of the experiments (Figure 3A). In all samples, an identical GC-poor group of microbiota could be detected (arrow-marked on Figure 3A), most probably representing the oral core microbiome.

454 pyrosequencing analysis of the microbiota co-incubated with an epithelial monolayer for 24 or 48 h, showed that irradiation induces a small increase (<1%) in Rothia, Granulicatella and Gemella species (Figure 3B; \( p_{\text{Rothia-24h}}=0.196, \ p_{\text{Granulicatella-24h}}=0.062, \ p_{\text{Gemella-24h}}=0.233, \ p_{\text{Rothia-48h}}=0.220, \ p_{\text{Granulicatella-48h}}=0.572, \ p_{\text{Gemella-48h}}=0.207 \)). Unlike Granulicatella and Gemella that are omnipresent in the oral cavity, Rothia is mostly linked with tooth surfaces [9]. Interestingly, Rothia species were reported to become more abundant in head and neck cancer patients during radiotherapy, whereas Granulicatella species were shown to decrease after irradiation [10,11]. Therefore Granulicatella species are not likely to be the causing agents of post-radiation diseases [11]. In contrast, different cases of Rothia bacteraemia have been reported of which 36% could be linked with oral mucositis [12].

In summary, our study shows that irradiation can affect the host-microbe crosstalk during wound healing, depending on the composition and functionality of the microbiota. A slight, although not significant, increase in abundance of Rothia after irradiation could be noticed in our in vitro system, which might be correlated with mucositis-related local and/or systemic infections observed in vivo.
Further research is necessary to determine which species are likely to have a negative impact on the recovery of the epithelium after irradiation and to develop new strategies to combat infections associated with radiotherapy-induced mucositis.
