Abstract

We report a case of a patient presenting with clinical, radiological and endoscopic features of colitis due to a compressive left para-aortic mass. Total open surgical excision was performed, which resulted in complete resolution of colitis. Histopathology and immunohistochemistry revealed benign retroperitoneal schwannoma. These neural sheath tumors rarely occur in the retroperitoneum. They are usually asymptomatic but as they enlarge they may compress adjacent structures, which leads to a wide spectrum of non-specific symptoms, including lumbar pain, headache, secondary hypertension, abdominal pain and renal colicky pain. CT and MR findings show characteristic features, but none are specific. Schwannoma can be isolated sporadic lesions, or associated with schwannomatosis or neurofibromatosis type II (NF2). Although they vary in biological and clinical behavior, their presence is, in nearly every case, due to alterations or absence of the NF2 gene, which is involved in the growth regulation of Schwann cells. Both conditions were excluded by thorough mutation analysis. Diagnosis is based on histopathological examination and immunohistochemistry. Total excision is therapeutic and has a good prognosis. Schwannomatosis and NF2 should be excluded through clinical diagnostic criteria. Genetic testing of NF2 is probably not justified in the presence of a solitary retroperitoneal schwannoma.

Key words: Colitis; Neurofibromatosis; Retroperitoneum; Schwannoma

INTRODUCTION

Schwannomas or neurilemmomas are encapsulated tumors arising from the neural sheath of peripheral nerves. They are usually present in the head and neck or in the upper extremities, but may appear in the posterior mediastinum and more rarely in the retroperitoneum. The latter are often found incidentally or may present with vague, non-specific symptoms if the tumor is large enough to compress surrounding structures.

We report a case of a benign retroperitoneal schwannoma with an unusual clinical presentation, its radiological, histopathological and genetic features, and its subsequent management.

CASE REPORT

A 45-year-old woman was admitted to our emergency department for severe colicky abdominal pain with nausea and vomiting that started about 15 min after her last meal. She had no relevant medical history but mentioned having had back pain for the last 2 mo, which she thought was due to her increasing workload and stress at work. She denied having any abdominal problems until that day. On clinical examination, the patient was afebrile, pale and uncomfortable. Blood pressure and heart rate were normal. Abdominal examination showed a diffusely tender abdomen, more pronounced in the left lower quadrant. She had no guarding or rebound. Deep palpation of the abdomen revealed a non-tender, non-pulsatile mass left of the umbilicus. Rectal examination was unremarkable, except for the presence of a little blood. Within the first hour after admission, the patient suffered one episode of diarrhea stained with a moderate amount of fresh blood. Laboratory tests showed an increased white blood cell count...
(WBC) of 18,000 cells/mm³ and C-reactive protein (CRP) of 1.1 mg/dL. Other values were within the normal range. At this point our differential diagnosis included diverticulitis and a contrast-enhanced computed tomodensitometry (CT) of the abdomen was performed. It revealed a diffuse infiltration around the rectum and the sigmoid colon, and a thickening of their walls (Figure 1). No diverticula were found. It also showed a well-demarcated, homogeneous, left para-aortic mass lying between the lumbar vertebrae and the left psoas muscle, which measured 60 × 50 mm (Figure 2). With few specific findings, the scan was considered inconclusive.

She was hospitalized and received isotonic fluid resuscitation, and intravenous broad-spectrum antibiotics were commenced. Symptoms improved rapidly and disappeared almost completely 3 d after the initial complaints. During her hospital stay, several examinations were performed. First, the patient underwent colonoscopy to exclude inflammatory bowel disease (IBD). It revealed a diffusely edematous, slightly erythematous rectum and sigmoid colon, but no erosive or ulcerative lesions. Histopathological examination of biopsies taken during colonoscopy showed diffuse edema and signs of chronic inflammation, characterized by the presence of mostly lymphocytes and polymuclear granulocytes. Granulomas were absent. A few cryptic abscesses and zones of erosion were also found. The pathologist’s diagnosis was chronic colitis, more pronounced in the sigmoid colon than the left colon, and excluded IBD. In laboratory tests, WBC had fallen to a normal value at 9780 cells/mm³ after a rise to 12,000. CRP level followed the same course to settle at 1.7 mg/dL, after it had risen to 10.8. Tumor markers CEA and CA 19.9 were within the normal range. Magnetic resonance imaging showed the same features as seen with CT scanning (Figure 3).

Since we believed that the mass caused the patient’s signs and symptoms, we opted for open surgical excision. We approached the retroperitoneal space through a median laparotomy. During exploration and meticulous dissection of the mass, we noticed that it was in close proximity to the aorta and left iliac artery and vein, and seemed to arise from the left para-aortic sympathetic chain. It also adhered partially to the left psoas muscle and to the anterior aspect of the lumbar vertebrae. Complete excision was performed. Perioperative examination of the mass revealed a solid, greyish, ovoid tumor with a smooth capsule and a homogeneous yellow core (Figure 4).

The postoperative course was uneventful. We noticed that the left leg was slightly warmer and dryer than the right, which suggested that we had performed a left lumbar sympathectomy, thus in favor of the excision of a tumor of neural origin. Microscopic histopathological examination revealed strings of spindle cells surrounded by a collagenous stroma that was partially hyalinized and showed cystic degeneration in some regions (Figure 5). There was some nuclear atypia with very limited mitotic activity, but
no signs of malignancy. The tumor tested intensely positive for S-100 protein, which confirmed the diagnosis of benign schwannoma. The integrity of the capsule was also noted, which confirmed total excision of the mass. The patient was discharged from the hospital on the fifth postoperative day.

Six weeks after surgery, she was still symptom free and signs of sympathectomy persisted. A CT scan and colonoscopy were performed to evaluate the evolution of colitis, which had completely resolved. Further investigations were performed to exclude neurofibromatosis type II (NF2) or schwannomatosis. Thorough physical examination was performed on the patient but no superficial tumors were found. Family history for schwannoma or meningioma was negative. MRI did not show any tumor of the central nervous system. Furthermore, the presence of a germline NF2 mutation was excluded by thorough mutation analysis on DNA extracted from the patient’s lymphocytes. We performed direct sequencing of all coding exons of the NF2 gene. Deletion was excluded by multiplex ligation-dependent probe amplification (MLPA). We concluded that the schwannoma was most likely due to a somatic mutation in the NF2 gene.

**DISCUSSION**

Schwannomas, or neurilemmomas, are tumors arising from the Schwann cells of peripheral nerves[4,6]. They are usually found in the head and neck or in the upper extremities. Only 1% is found in the retroperitoneum, which accounts for 0.5%-1.2% of all retroperitoneal tumors[3,4]. They can be isolated as sporadic lesions or associated with schwannomatosis or NF2. Although they vary in biological and clinical behavior, their presence is in nearly every case due to alterations or absence of the NF2 gene (located on chromosome 22q12), which codes for merlin, a tumor suppressor protein involved in the growth regulation of Schwann cells, but its exact mechanism has not yet been elucidated.

Most schwannomas are benign but (although very rarely) malignant degeneration can occur, and is usually associated with NF2[4]. Patients with benign retroperitoneal schwannomas are predominantly in their second to fifth decade, and women are twice as often affected as men[4].

On gross appearance, schwannomas are well-demarcated, solid tumors with a smooth surface and have an ovoid or spherical shape[3]. Sometimes, secondary changes such as hemorrhage, cysts and calcification can be present[1]. They are usually solitary and slow-growing tumors[3]. The retroperitoneum is non-restrictive, so that benign tumors are often able to grow to a large size before causing symptoms. These are generally vague and non-specific[7], and range from lumbar pain and neurological symptoms in the lower extremities[8], to renal colicky pain, with or without hematuria, if it involves the urogenital tract[9]. Abdominal complaints can also occur but are mainly vague and poorly localized, with some digestive disturbances[8,10,11].

Our patient’s presentation was peculiar, not only because of the abrupt onset of her symptoms, but also because she had colitis. We believe that the tumor was large enough to compromise venous return in the mesocolon, which led to stasis characterized by the infiltration and parietal thickening seen on CT, the edematous and erythematous aspect seen during colonoscopy, and the chronic inflammation with edema seen on histopathological examination. This idea has been strengthened by the fact that those signs disappeared completely after removal of the tumor.

Diagnosis is rarely made preoperatively. The mass seen on the CT scan showed characteristic features of benign schwannoma. It was a well-demarcated, spherical, solitary mass and in a paravertebral position[8]. Contrast enhancement homogeneity was seen because no gross cystic degeneration or calcification had yet occurred. Most authors agree that these features are not diagnostic. Other diagnoses such as paraganglioma, neurofibroma, ganglioneuroma, tumors of mesothelial origin and retroperitoneal malignancies, including malignant fibrous histiocytoma, lymphoma and liposarcoma, should be considered[12,13]. MRI was helpful because it has a better definition, multiplanar capabilities, and the possibility to differentiate the nature of the tumor, such as solid tissue, fibrous tissue, simple or atypical fluid, and blood[14]. It confirmed the presence of a solid, homogeneous mass, and showed its relation to adjacent structures in greater detail[15,16]. No invasive process was revealed and the margins were still regular, convincing us that the mass was benign in nature[16]. Definite diagnosis was made during histopathological examination and immunohistochemistry. Microscopically, the mass showed Antoni A (well-organised spindle cells in a palisade pattern) and Antoni B area (less cellular, loose pleomorphic cells) on the left (HE, × 200).

sequencing of all coding exons of the NF2 gene. Deletion was excluded by MLPA. This mutation detection strategy, ideally performed on the original tumor specimen, allows for the identification of mutations in the NF2 gene in schwannomatosis. Deletion of the NF2 gene in schwannomatosis is a rare cause of digestive tract symptoms.
