Some contributions to incidence geometry and the polynomial method

Anurag Bishnoi
SOME CONTRIBUTIONS TO INCIDENCE GEOMETRY AND THE POLYNOMIAL METHOD

ANURAG BISHNOI

Promotor: Prof. Dr. Bart De Bruyn

A thesis presented for the degree of
Doctor of Sciences

Department of Mathematics
Ghent University
Belgium

2016-2017
Preface

The work presented in this thesis falls under two main topics, *Incidence Geometry* and *Polynomial Method*. The former deals with incidence structures that are motivated by geometrical notions like projective spaces, affine spaces and polar spaces, while the latter is a loosely defined mathematical technique of using polynomials to solve problems in combinatorics, finite geometry, discrete geometry and number theory. The thesis is accordingly divided into two parts which can be read independently of each other:

I Incidence Geometry: Chapters 1 to 6.

II Polynomial Method: Chapters 7 to 9.

The incidence structures that we will be dealing with in the first part of the thesis are *generalized polygons* and *near polygons*, while the polynomial method in the second part is related to zeros of an $n$ variable polynomial over a ring $R$ in certain finite subsets of $R^n$, which we will call *grids*.

I started my thesis work in August 2013 by learning the theory of *valuations* of generalized polygons which was developed by my supervisor Bart De Bruyn to obtain characterizations of small generalized polygons. He had successfully applied this theory to prove a spectacular result that the Ree-Tits octagon of order $(2,4)$ is the unique generalized octagon of order $(2,4)$ which contains a suboctagon of order $(2,1)$. The basic idea in this theory is to first compute certain integer valued functions on the point set of a given generalized polygon, the so-called *valuations*, and a particular incidence structure formed by these valuations called the *valuation geometry* of the generalized polygon. This valuation geometry is then used to obtain the required information about every generalized polygon that contains the given generalized polygon as a full subgeometry. He saw further potential in this theory and gave me a result on semi-finite generalized hexagons, which he knew how to prove, as a “toy problem” that I could work on after mastering the techniques that he had developed. At around November 2013, I successfully solved this problem, which I consider as my first milestone in mathematical research. We had proved that (a) no (possibly infinite) generalized hexagon can contain the split Cayley hexagon $H(2)$ as a proper full subgeometry, and (b) every generalized hexagon containing the dual split Cayley hexagon $H(2)D$ as a proper full subgeometry is finite, and hence isomorphic to the dual twisted triality hexagon $T(2,8)$ by the classification result of Cohen and Tits. Within a couple of months we generalized the techniques further so that we could prove similar results for *near hexagons* (which are more general than generalized hexagons) containing these subhexagons. This work became my first research paper. We have recently extended our results further by considering generalized hexagons with $q + 1 \in \{4, 5\}$ points on each line containing one of the known generalized hexagons of order $q$ as a subgeometry. All of these results constitute Chapter 4 of this thesis.

As an offshoot of our work on semi-finite generalized polygons, Bart and I thought it would be nice to compute the valuation geometry of some other well-known near polygons with
three points on each line (many of our techniques were limited to point-line geometries with three points on each line). The most natural choice for us was the Hall-Janko near octagon $\text{HJ}$, which corresponds to the sporadic finite simple group $J_2$ and contains subgeometries isomorphic $H(2)^D$. I computed the valuation geometry of $\text{HJ}$, and as a result we noticed that there might exist a near octagon with three points on each line containing $\text{HJ}$ which can be constructed using certain valuations of $\text{HJ}$. Since there was no known example of such a near octagon, this was unexpected (and exciting!). I checked, using a computer, that indeed we have a near octagon containing $\text{HJ}$, and quickly started finding its properties with the help of the mathematical software SageMath. My computations revealed that the automorphism group of this new near octagon acted vertex-transitively on the collinearity graph, which was a bit surprising due to the asymmetrical nature of our construction using certain valuations of $\text{HJ}$. Moreover, SageMath gave me the order of the full automorphism group and the fact that its derived subgroup is a simple group. From this we conjectured that the automorphism group of our new near octagon must be isomorphic to $G_2(4):2$, where $G_2(4)$ is the well-known finite simple group of Lie type. We finally arrived at a group theoretical construction of this near octagon using central involutions of $G_2(4):2$ and proved our conjecture. Sitting inside this new near octagon, we discovered another new near octagon, which corresponds to the finite simple group $L_3(4)$ (the projective special linear group). Both of these near octagons are new and they share many common properties; for example, both of them can be defined by a suborbit diagram of central involutions which look quite similar. We give a common treatment of these two new incidence geometries in Chapter 5, where we derive several important structural properties.

The new near octagon corresponding to the group $G_2(4)$, let’s call it $O_1$, has $\text{HJ}$ as a subgeometry, which in turn has $H(2)^D$ has a subgeometry. In this manner we get a “tower” of near polygons, $H(2,1) \subset H(2)^D \subset \text{HJ} \subset O_1$, where $H(2,1)$ is the unique generalized hexagon of order $(2,1)$ (it is the dual of the incidence graph of Fano plane). The automorphism groups of these near polygons are $L_3(2):2$, $U_3(3):2$, $J_2:2$ and $G_2(4):2$, respectively. Thus we have the first four members of the Suzuki tower of finite simple groups, $L_3(2) < U_3(3) < J_2 < G_2(4) < \text{Suz}$, where $\text{Suz}$ is the sporadic simple group discovered by Michio Suzuki in 1969. Suzuki constructed $\text{Suz}$ as an automorphism group of the largest graph in a sequence $\Gamma_0, \ldots, \Gamma_4$ of graphs in which $\Gamma_1, \ldots, \Gamma_4$ are strongly regular graphs and for each $i \in \{0, \ldots, 3\}$, the graph $\Gamma_i$ is the local graph of $\Gamma_{i+1}$. Using our Suzuki tower of near polygons, we can show that all of these graphs can be constructed in a uniform geometrical fashion. Moreover, we have proved that every near polygon in this tower, except the first one, is the unique near polygon of its order and diameter containing the previous near octagon as a subgeometry. These results constitute Chapter 6 of the thesis.

A significant part of my work in incidence geometry involved computations on computer models of near polygons and generalized polygons using mathematical software like GAP and SageMath. We had to design reasonably fast ways of finding certain substructures of near polygons called hyperplanes, which would then be used to construct the valuation geometry of a given near polygon. While working on these algorithms, I realised that they can help us answer some open questions on distance-$j$ ovoids of generalized polygons. In collaboration with Ferdinand Ihringer, I was able to show non-existence of distance-2 ovoids in the dual split Cayley hexagon $H(4)^D$. The techniques that we developed for this work are quite general and they might be helpful in resolving other such “small cases” of
open problems in finite geometry. All my computational work, some of which is required in subsequent chapters, is contained in Chapter 3.

Towards the end of 2014, I started getting interested in the so-called polynomial method after reading Terence Tao’s blog post on Zeev Dvir’s two page solution of the famous finite field Kakeya problem using a slick polynomial argument. I quickly learned about Noga Alon’s Combinatorial Nullstellensatz, Tom H. Koornwinder’s proof of the absolute bound on equiangular lines, Andries Brouwer and Lex Schrijver’s proof of the bound on affine blocking sets, and several other such important results involving (elementary) polynomial arguments. By March 2015, I started writing some notes on the polynomial method in collaboration with my friends Abhishek Khetan and Aditya Potukuchi who were also interested in understanding these techniques. We read several papers and expository articles to get acquainted with some of the basic ideas involved. In particular, we started reading the papers “Combinatorial Nullstellensatz Revisited” by Pete Clark and “Warning’s Second Theorem with Restricted Variables” by Pete Clark, Aden Forrow and John Schmitt. In April 2015, I emailed Pete and John saying that one can easily obtain a generalization of the classical Chevalley-Warning theorem (which is a corollary of Warning’s second theorem) using a result of Simeon Ball and Oriol Serra called the Punctured Combinatorial Nullstellensatz. My new result is in fact a generalization of David Brink’s restricted variable Chevalley-Warning theorem, which he proved using Alon’s Combinatorial Nullstellensatz. We give the exact statement in Chapter 8 where we also lay down the basics of grid reduction of polynomials and give a new proof of Punctured Combinatorial Nullstellensatz.

Pete and John responded promptly to my email(s) and shared with me a lot of material related to the things they have been working on. The discussions that followed with Pete, John and Aditya resulted in a collaborative work which I believe is my main contribution to the polynomial method. The main tool used by Clark, Forrow and Schmitt to obtain their generalization of Warning’s second theorem on the minimum number of common zeros of a system of polynomial equations over a finite field is a result of Alon and Füredi from 1993 that gives a lower bound on the number of non-zeros of a polynomial in a finite grid. They gave several combinatorial applications of their result along the general theme of refining “combinatorial existence theorems into theorems which give explicit (and sometimes sharp) lower bounds on the number of combinatorial objects asserted to exist”. Within a few weeks of our discussions, I noticed that this Alon-Füredi theorem is in fact related to Reed-Muller type affine variety codes, and to the famous Schwartz-Zippel lemma. I also came up with an alternate proof of the Alon-Füredi theorem, and then Aditya discovered an even simpler proof which helped me in obtaining a new generalization of the Alon-Füredi theorem. Ultimately, we discovered a lot more about this result and its connection with different areas of mathematics, including incidence geometry. All of this work is contained in the last chapter, Chapter 9.
Acknowledgements

I would like to thank Bart De Bruyn for being a great supervisor during the past three years. He read, and re-read, all of my work, and always gave valuable inputs. Nothing in Part I of the thesis would have been possible without him helping me identify the right problems to work on.

I would like to thank Pete Clark and John Schmitt for several helpful discussions during my PhD. My collaboration with them, which led to the second part of my thesis, has been a great learning experience.

Aditya Potukuchi deserves a special thanks for being a great friend (and a co-author) who listened to a lot my ramblings over the years. Mathematical discussions with him and Abhishek Khetan, who I would also like to thank, have been a crucial part of my PhD experience.

Another friend + co-author who deserves thanks is Ferdinand Ihringer. After my supervisor, he is probably the person who knows the most about my research work. Over the years, we discussed several problems in finite geometry, which in particular motivated me to learn some interesting topics that I was unfamiliar with. Inputs from John Bamberg in the problems that Ferdinand and I worked on were also quite helpful, and I thank him for that.

In a lot of my research work, I have used the free open-source softwares SageMath and GAP. I am grateful to the creators and developers of these mathematical softwares for their great service to the mathematical community, without whom I would not have been able to discover many of the results contained in this thesis.

I am indebted to Prof. Bhaskar Bagchi for introducing me to Incidence Geometry. My research interests have been shaped by the 2 months I spent with him as a summer research fellow at the Indian Statistical Institute, Bangalore, and I thank the Indian Academy of Sciences for giving me that opportunity. I thank Prof. Bagchi for all the valuable lessons he taught me and for informing me about the Incidence Geometry research group at Ghent University.

I can’t imagine learning geometry so well without coming to this department at Ghent which has developed a great tradition in the area. Thus, I thank all the mathematicians who have contributed to the development of this research group. I would also like to thank the department secretary Samuel Perez for helping me in many different ways and handling all the paperwork.

I thank all my jury members, Bart De Bruyn, Simeon Ball, Bruce Cooperstein, Hendrik Van Maldeghem, Leo Storme and Koen Thas, for reading this thesis carefully and making valuable comments.
On a personal level, I thank my friends and colleagues who have been responsible for the wonderful time that I have had here in the past three years: Aparajita, Anwesha, Manuel, Ana, Annelies, Hendrik, Pauline, Paul (Russel), Paul (Shafer), John, Morgan, Ursula, Charlotte, Ewa, Magali, Anamari, Andrea, Frank, Geertrui, Maarten, Wouter, Marianna, Rico, Alice, Matteo, Surya, Daniele, ... Also, a special thanks to all my friends back home in India, who I visited every year and always had a great time with.

Above all, I thank my parents, my brother, and my sister for the love and support they have given me all my life.
Publications

There are seven publications related to the work presented in this thesis [18, 24]. At the time of writing this thesis, three of these [19, 21, 23] have been published, three [18, 22, 24] are under review, and one [20] is under preparation.

- Chapters 3 and 4 are based on 22, 23 and 24.
- Chapter 5 is based on 20 and 21.
- Chapter 6 is based on 19.
- Chapter 8 contains an unpublished result (Theorem 8.3.1).
- Chapter 9 is based on 18.

These references and remarks will not be repeated in individual chapters.

Part I.

Incidence Geometry
1. Preliminaries

We assume a basic level of familiarity with linear algebra, projective geometry, graph theory and group theory (especially group actions and permutation groups). Here we note down some definitions and results related to the main players of the first part of this thesis, generalized polygons and near polygons.

1.1. Point-Line Geometries

A **point-line geometry** is a triple \( S = (\mathcal{P}, \mathcal{L}, I) \) of sets where \( \mathcal{P} \) is non-empty, \( \mathcal{P} \) and \( \mathcal{L} \) are disjoint and \( I \) is a subset of \( \mathcal{P} \times \mathcal{L} \) such that for every \( L \in \mathcal{L} \) there exist at least two \( x \in \mathcal{P} \) for which \( (x, L) \in I \). We refer to the elements of \( \mathcal{P} \) as **points** of \( S \), elements of \( \mathcal{L} \) as **lines** of \( S \) and \( I \) as the **incidence** relation between the points and lines. We will often use geometrical language by writing the statement \( (x, L) \in I \) as “the point \( x \) and the line \( L \) are incident”, “the point \( x \) lies on the line \( L \)”, “the line \( L \) contains the point \( x \)”, etc. Two points \( x, y \) are called **collinear** if there is a line \( L \) incident with both \( x \) and \( y \). We say that a point-line geometry has **order** \((s, t)\), for possibly infinite cardinal numbers \( s \) and \( t \), if every line is incident with \( s + 1 \) points and every point is incident with \( t + 1 \) lines. If \( s = t \), then we simply say that the point-line geometry has order \( s \). When every point is incident with at least three lines and every line is incident with at least three points, we call the point-line geometry **thick**. The **point-line dual** of a point-line geometry \( S = (\mathcal{P}, \mathcal{L}, I) \), when \( \mathcal{L} \) is non-empty and every point is incident with at least two lines, is the point-line geometry \( S^D = (\mathcal{P}^D, \mathcal{L}^D, I^D) \) where \( \mathcal{P}^D = \mathcal{L} \), \( \mathcal{L}^D = \mathcal{P} \), \( I^D \subseteq \mathcal{L} \times \mathcal{P} \) and \( (L, x) \in I^D \) if and only if \( (x, L) \in I \).

A point-line geometry \( S \) is called a **partial linear space** if for every pair of distinct points in \( S \), there is at most one line which contains both of these points. When there is exactly one line through every pair of distinct points, we get a **linear space**. Important examples of linear spaces are **projective spaces** and **affine spaces**. When a point-line geometry \( (\mathcal{P}, \mathcal{L}, I) \) satisfies the condition that \( \{x \in \mathcal{P} \mid x \ I \ L_1\} \neq \{x \in \mathcal{P} \mid x \ I \ L_2\} \) for every \( L_1 \neq L_2 \in \mathcal{L} \), we can uniquely identify each line with the set of points that are incidence with it, and thus we get a hypergraph \( (V, E) \) corresponding to the geometry, where \( V = \mathcal{P} \) and \( E = \{\{x \in \mathcal{P} \mid x \ I \ L\} \mid L \in \mathcal{L}\} \). For partial linear spaces this condition is automatically satisfied; hence we can, and often will, treat a partial linear space like a hypergraph with the incidence relation being set containment.

Let \( S = (\mathcal{P}, \mathcal{L}, I) \) be a point-line geometry. The **incidence graph** of \( S \) is the graph whose vertex set is \( \mathcal{P} \cup \mathcal{L} \) and two vertices are adjacent when they are incident in \( S \). The **point graph** or **collinearity graph** of \( S \) is the graph whose vertex set is \( \mathcal{P} \) and two vertices are adjacent when they are collinear. The distance function on pairs of vertices of the incidence graph will be denoted by \( \delta_S(\cdot, \cdot) \), while the distance function on pairs of vertices of the collinearity graph will be denoted by \( d_S(\cdot, \cdot) \). When no confusion arises we will...
Preliminaries

Figure 1.1.: The unique GQ of order \((2, 2)\)

simply write \(\delta\) and \(d\), without the subscript. We call the geometry \(S\) connected if the diameter of its incidence graph, or equivalently the diameter of its collinearity graph, is finite. For a point \(x\) and a line \(L\), we define \(d(x, L)\) as \(\min\{d(x, y) \mid y \in L\}\), and for two lines \(L, M\), we define \(d(L, M)\) as \(\min\{d(x, y) \mid x \in L, y \in M\}\). For two nonempty subsets \(A, B\) of \(P\), we define \(d(A, B)\) as \(\min\{d(x, y) \mid x \in A, y \in B\}\). When \(A\) is a singleton \(\{x\}\), we simply denote \(d(\{x\}, B)\) as \(d(x, B)\). Let \(\Gamma\) denote the collinearity graph of \(S\). Then the set of points at distance \(i\) (at most \(i\)) from a point/line/subset \(X\) in \(\Gamma\) is denoted by \(\Gamma^i(X)\) (respectively \(\Gamma_{\leq i}(X)\)). Unless stated otherwise, the distances measured in this thesis will be in the collinearity graph of a point-line geometry. The following proposition relates the two distance functions \(d\) and \(\delta\) of \(S\). We leave its proof to the reader.

**Proposition 1.1.1.** Let \((P, L, I)\) be a connected point-line geometry, let \(\delta(\cdot, \cdot)\) denote the distance function in its incidence graph and let \(d(\cdot, \cdot)\) denote the distance function in its collinearity graph. Let \(x, y \in P\) and \(L, M \in L\) with \(L \neq M\). Then we have \(\delta(x, y) = 2 \cdot d(x, y)\), \(\delta(x, L) = 2 \cdot d(x, L) + 1\) and \(\delta(L, M) = 2 \cdot d(L, M) + 2\).

Two point-line geometries \((P, L, I)\) and \((P', L', I')\) are called isomorphic if there exists a bijective map \(f : P \cup L \to P' \cup L'\) such that \(f(P) = P', f(L) = L'\) and \((x, L) \in I\) if and only if \((f(x), f(L)) \in I'\). An isomorphism from a point-line geometry to itself is called an automorphism, and the group formed by all automorphisms is called the automorphism group of the geometry.

**Example.** Let \(P\) be the set of all two element subsets of \(\{1, 2, 3, 4, 5, 6\}\) and \(L\) the set of all partitions of \(\{1, 2, 3, 4, 5, 6\}\) into two element subsets. Then by taking incidence relation \(I\) as set containment, we get a point-line geometry \((P, L, I)\) of order \((2, 2)\) with 15 points and 15 lines. This point-line geometry is isomorphic to its point-line dual and has the automorphism group isomorphic to the symmetric group \(S_6\). In Figure 1.1 we have given a drawing of this geometry which explains the common name given to it, **Doily** (the 15 lines are the 5 lines of the regular pentagon, 5 angle bisectors and 5 incomplete circles). As we will see in the next section, this point-line geometry is an example of a generalized quadrangle. In fact, this is the unique generalized quadrangle of order \((2, 2)\) up to isomorphism.

\footnote{For any arbitrary graph \(\Gamma\), we denote the set of vertices at distance \(i\) from a given vertex \(x\) by \(\Gamma_i(x)\).}
A point-line geometry \( S = (P, L, I) \) is called a subgeometry of another point-line geometry \( S' = (P', L', I') \) if \( P \subseteq P' \), \( L \subseteq L' \) and \( I = I' \cap (P \times L) \). The subgeometry is called full if for every line \( L \in L \), the set \( \{ x \in P \mid x \ I \ L \} \) is equal to the set \( \{ x \in P' \mid x \ I' \ L \} \). It is called isometrically embedded if the distances measured in the collinearity graph of \( S \) are equal to the distances in the collinearity graph of \( S' \), i.e., for every pair of points \( x, y \) in \( S \), we have \( d_S(x, y) = d_{S'}(x, y) \). Figure 1.2 shows a full isometrically embedded subgeometry of Doily. The subgeometry is in fact isomorphic to the unique generalized quadrangle of order \( (2, 1) \). By abuse of notation, we will denote the set \( \Gamma_i(P) \) of points of \( S' \) at distance \( i \) from \( P \) by \( \Gamma_i(S) \).

The books [72], [92] and [125] are some of the standard references for point-line geometries. For an introduction to incidence geometry, see [12] and [63].

### 1.2. Generalized Polygons

Generalized polygons were introduced by Tits in the Appendix of his famous paper on triality [136], and they are now an integral part of incidence geometry. They have connections with several areas of mathematics like group theory, extremal graph theory, coding theory and design theory. The standard reference for generalized polygons is [138], and the older survey by Kantor [94, Section A] gives a succinct introduction to the basic theory of these point-line geometries. For proofs of statements in this section which are stated without a proof, we refer to [138] and [63, Chapter 5].

One of the easiest ways to define generalized polygons is as follows.

**Definition.** For an integer \( n \geq 2 \), a generalized \( n \)-gon is a point-line geometry whose incidence graph has diameter \( n \) and girth \( 2n \).\(^2\)

A generalized polygon is a generalized \( n \)-gon for some integer \( n \geq 2 \). Note that a bipartite graph of diameter \( n \) which contains a cycle has girth (length of the shortest cycle) at most \( 2n \). Therefore, generalized polygons correspond to bipartite non-tree graphs of a given

\(^2\)Sometimes the condition that every vertex of the incidence graph has degree at least \( 3 \) is also added, for example in [94]. We will simply call the generalized polygons satisfying that condition as thick generalized polygons.
diameter and maximum possible girth, the so-called bipartite Moore graphs [85, Chapter 5]. From the definition it directly follows that the point-line dual of a generalized n-gon is also a generalized n-gon. A generalized 2-gon is simply a point-line geometry whose incidence graph is a complete bipartite graph. A generalized 3-gon (triangle) is equivalent to a possibly degenerate projective plane. Generalized quadrangles as defined above can be shown to be equivalent to partial linear spaces satisfying the following axioms:

GQ1 there exist at least two disjoint lines;
GQ2 for every point x and a line L not containing x, there exists a unique point \( \pi(x) \) on L which is collinear with x.

Similarly, we have the following equivalent definition of generalized \( n \)-gons for any \( n \geq 3 \).

An ordinary \( n \)-gon for \( n \in \mathbb{N} \{0, 1, 2\} \) is a point-line geometry which is isomorphic to the partial linear space that has point set \( \{1, \ldots, n\} \), line set \( \{\{1, 2\}, \{2, 3\}, \ldots, \{n-1, n\}, \{n, 1\}\} \) and set containment as incidence relation. A generalized \( n \)-gon with \( n \in \mathbb{N} \{0, 1, 2\} \) is a partial linear space \( S = (P, L, I) \) satisfying:

GP1 \( S \) has no subgeometries that are ordinary \( m \)-gons with \( m \in \{3, 4, \ldots, n-1\} \);
GP2 \( S \) has subgeometries that are ordinary \( n \)-gons;
GP3 for every \( X, Y \in P \cup L \) with \( X \neq Y \), there exists a subgeometry of \( S \) containing \( X \) and \( Y \) which is isomorphic to an ordinary \( n \)-gon.

One of the most basic properties of thick generalized polygons is that they have an order. We state it here without proof.

**Proposition 1.2.1.** Let \( S \) be a generalized \( n \)-gon for \( n \in \mathbb{N} \{0, 1, 2\} \) and let \( \tilde{\Gamma} \) be its incidence graph.

1. For every two vertices \( u \) and \( v \) of \( \tilde{\Gamma} \) at maximal distance \( n \) from each other, there exists a bijection between the set of neighbors of \( u \) and the set of neighbors of \( v \).
2. If \( S \) is thick, then \( S \) has an order \((s, t)\). Moreover, if \( n \) is odd, then \( s = t \).
3. \( S \) is thick if and only if it has ordinary \((n+1)\)-gons as subgeometries.

For generalized quadrangles, we can say something more. An \((n_1 \times n_2)\)-grid, with \( n_1, n_2 \in \mathbb{N} \{0, 1\} \), is a point-line geometry that is isomorphic to the partial linear space whose point set is equal to \( \{1, \ldots, n_1\} \times \{1, \ldots, n_2\} \) and whose lines are all sets of the form \( \{i\} \times \{1, \ldots, n_2\} \) for \( i \in \{1, \ldots, n_1\} \) and those of the form \( \{1, \ldots, n_1\} \times \{i\} \) for \( i \in \{1, \ldots, n_2\} \). If \( n_1 = n_2 \), then we call the grid symmetrical and otherwise it is nonsymmetrical. The point-line dual of a symmetrical/nonsymmetrical grid is called a symmetrical/nonsymmetrical dual grid.

**Proposition 1.2.2** ([63, Theorem 5.16]). If \( S \) is a finite generalized quadrangle in which every point is incident with precisely two lines, then \( S \) is a grid. Dually, if \( S \) is a finite generalized quadrangle in which every line is incident with precisely two points, then \( S \) is a dual grid.

**Proposition 1.2.3** ([63, Theorem 5.17]). Let \( S \) be a finite generalized quadrangle. Then precisely one of the following holds.

1. \( S \) is a nonsymmetrical grid.
(2) $S$ is a nonsymmetrical dual grid.

(3) $S$ has an order $(s,t)$.

In finite generalized polygons with an order, we can do elementary counting to obtain the total number of points and lines. This information is collected in the following result.

**Proposition 1.2.4** (Lemma 1.5.4). Let $S = (P,L,I)$ be a finite generalized $n$-gon of order $(s,t)$ with $n \geq 3$ and let $x$ be a point of $S$. For $i \in \{0,\ldots,n\}$, let $S_i(x)$ denote the set of elements of $P \cup L$ that are at distance $i$ from $x$ in the incidence graph of $S$. Then

1. For $1 \leq i \leq n-1$, we have $|S_i(x)| = (t+1)s^{(i/2)}t^{((i-1)/2)}$ for $n$ even while $|S_n(x)| = s^{n-1}t^{n/2-1}$ for $n$ odd.
2. If $n$ is even, then
   \[ |P| = (s+1)\frac{(st)^{\frac{n}{2}} - 1}{st - 1} \quad \text{and} \quad |L| = (t+1)\frac{(st)^{\frac{n}{2}} - 1}{st - 1}; \]
3. If $n$ is odd, then $s = t$ and
   \[ |P| = |L| = \frac{s^n - 1}{s - 1}. \]

Since subgeometries of a generalized polygon are going to play an important role in this thesis, we include the following results.

**Lemma 1.2.5.** Let $S$ be a generalized $2n$-gon contained in another generalized $2n$-gon $S'$ as a full subgeometry. Then $S$ is isometrically embedded in $S'$.

**Proof.** If there are two points $x,y$ in $S$ such that $\lfloor n/2 \rfloor \geq d_S(x,y) > d_S(x,y)$, then we will get a subgeometry of $S'$ isomorphic to an ordinary $m$-gon for some $m < n$. \(\square\)

Two points/lines of a generalized $2n$-gon are called opposite if they lie at distance $2n$ from each other in the incidence graph. By Proposition 1.1.1, two points of a generalized $2n$-gon are opposite if and only if they are at distance $n$ from each other in the collinearity graph, and two lines are opposite if and only if they are at distance $n-1$ from each other in the collinearity graph. Proposition 1.2.1(1) implies that opposite lines in a generalized $2n$-gon have the same number of points on them and that opposite points have the same number of lines through them. Note that for every point $x$ and every line $L$ of a generalized $2n$-gon, there exists a unique point $\pi_L(x)$ on $L$ which is nearest to $x$, i.e., for every point $y$ on $L$ with $y \neq \pi_L(x)$ we have $d(x,y) = d(x,\pi_L(x)) + 1$.

**Lemma 1.2.6.** Let $S$ be a generalized $2n$-gon that is contained in a generalized $2n$-gon $S'$ as a full subgeometry. Then:

1. every point of $S'$ is opposite to a point of $S$;
2. every line of $S'$ is opposite to a line of $S$;
3. if $S$ is thick, then $S'$ is thick (and hence has an order).

\[\text{The condition of being a full subgeometry is not necessary here, but we include it because all our subgeometries will be full.}\]
Preliminaries

Proof. (1) Let \( x \) be a point of \( S' \) and let \( y \) be a point of \( S \) at distance \( i := d(x, S) \) from \( x \) (by Lemma 1.2.5 we can simply denote the distance functions \( d_{S'} \) and \( d_S \) by \( d \)). Let \( z \) be a point of \( S \) which is at distance \( n - i \) from \( y \). Then there cannot exist any path of length less than \( n \) between \( x \) and \( z \) as otherwise we will get an ordinary \( m \)-gon as a subgeometry for some \( m < n \), which is not possible since \( S' \) is a generalized \( n \)-gon. Therefore, \( d(x, z) = n \), i.e., \( x \) and \( z \) are opposite.

(2) Let \( L \) be a line of \( S' \) and \( x \) an arbitrary point on \( L \). By (1), there exists a point \( z \) in \( S \) which is opposite to \( x \). Let \( \pi_L(z) \) be the unique point on \( L \) nearest to \( z \). Then \( d(z, \pi_L(x)) = n - 1 \). There exists a unique line through \( z \) which contains a point at distance \( n - 2 \) from \( \pi_L(z) \). Let \( L' \) be any other line through \( z \) which is contained in \( S \). Then we must have \( d(L', L) = n - 1 \), i.e., \( L \) and \( L' \) are opposite.

(3) This now follows from Proposition 1.2.1(1).

\[ \square \]

1.2.1. Important Examples

For every field \( \mathbb{F} \), we have the Desarguesian projective plane \( \text{PG}(2, \mathbb{F}) \) constructed from the vector space \( \mathbb{F}^3 \) by taking the 1-dimensional subspaces as points and 2-dimensional subspaces as lines, with incidence as set containment. This is a generalized triangle. When \( \mathbb{F} \) is the finite field of order \( q \), for some prime power \( q \), then we get a finite generalized triangle of order \( q \) which has \( 1 + q + q^2 \) points and equally many lines.

Every nonsingular quadric of Witt index 2 gives rise to a generalized quadrangle if we take the points to be the 1-dimensional subspaces contained in the quadric, and lines to be the 2-dimensional subspaces contained in the quadric. In fact, every rank 2 polar space is a generalized quadrangle (see [63, Chapter 7] or [12, Chapter 4] for an introduction to polar spaces). For example, the generalized quadrangle given in Figure 1.1 can be obtained from the symplectic polarity of \( \text{PG}(3, 2) \) defined by the alternating bilinear form \( f((x_0, x_1, x_2, x_3) \cdot (y_0, y_1, y_2, y_3)) = x_0y_1 - x_1y_0 + x_2y_3 - x_3y_2 \) (the map \( U \mapsto \{ x \in \text{PG}(3, 2) \mid f(x, u) = 0 \ \forall u \in U \} \) gives the polarity), and it is denoted by \( W(2) \). For more on generalized quadrangles see the standard reference [116].

There is a natural doubling construction which allows us to construct generalized \( 2n \)-gons from generalized \( n \)-gons. Let \( S = (\mathcal{P}, \mathcal{L}, I) \) be a point-line geometry. Then the double of \( S \) is the point-line geometry \( S' = (\mathcal{P}', \mathcal{L}', I') \) where \( \mathcal{P}' = \mathcal{P} \cup \mathcal{L} \) and \( \mathcal{L}' \) is the set of all sets \( \{ x, L \} \) where \( (x, L) \in I \) and \( I' \) is set containment. It can be easily shown that if \( S \) is a generalized \( n \)-gon, then its double is a generalized \( 2n \)-gon in which every line is incident with precisely two points. In fact, the converse also holds. Every generalized \( 2n \)-gon with two points on each line is the double of a generalized \( n \)-gon. Therefore, we get a generalized hexagon \( H_π \) by doubling a projective plane \( \pi \). If \( \pi \) is isomorphic to \( \text{PG}(2, q) \), then we denote \( H_π \) by \( \text{H}(1, q) \), noting that this generalized hexagon has order \((1, q)\). The dual of \( \text{H}(1, q) \) will be denoted by \( \text{H}(q, 1) \); thus the points of \( \text{H}(q, 1) \) are the edges of the incidence graph of \( \text{PG}(2, q) \) (the flags of the projective plane), and the lines are the vertices of the incidence graph. The automorphism group of \( \text{H}(q, 1) \) is isomorphic

\[ \text{"This is basically the incidence graph of } S \text{ treated as a point-line geometry in itself."} \]
to a semi-direct product $P\Gamma L_3(q) \rtimes C_2$, and thus has size $2r(q^3 - 1)(q^3 - q)(q^3 - q^2)/(q - 1)$ when $q$ is the $r$-th power of a prime.

Let $L$ be a 2-dimensional subspace of $\mathbb{F}_q^{n+1}$ (or equivalently a line of the $n$-dimensional projective space $\text{PG}(n, q)$), where $q$ is a prime power. Let $x = (x_0, \ldots, x_n)$ and $y = (y_0, \ldots, y_n)$ form a basis of $L$. Then the Grassmann coordinates of $L$ are $p_{ij} = x_i y_j - x_j y_i$ for $0 \leq i < j \leq n$. Note that these coordinates are independent of the choice of basis of $L$, up to a scalar factor. Thus, the Grassman coordinates map a line of $\text{PG}(n, q)$ to a point of $\text{PG}(\binom{n+1}{2} - 1, q)$. The split Cayley hexagon $H(q)$ is a generalized hexagon of order $(q, q)$, when $q$ is a prime power, which can be defined as follows [136, 138, Section 2.4.13]. Consider the quadratic form $Q : \mathbb{F}_q^7 \to \mathbb{F}_q$ defined as $Q(x) = x_0 x_4 + x_1 x_5 + x_2 x_6 - x_3^2$.

(a) The points of $H(q)$ are all 1-dimensional subspaces of $\mathbb{F}_q^7$ which vanish on $Q$.

(b) The lines of $H(q)$ are all 2-dimensional subspaces of $\mathbb{F}_q^7$ which vanish on $Q$, and whose Grassmann coordinates satisfy $p_{12} = p_{34}, p_{54} = p_{32}, p_{20} = p_{35}, p_{65} = p_{30}, p_{01} = p_{36}$ and $p_{46} = p_{31}$.

We will not be using this definition directly in this thesis, but only some of the well-known properties of split Cayley hexagons. The automorphism group of $H(q)$ is isomorphic to the semi-direct product $G_2(q) \rtimes \text{Aut}(\mathbb{F}_q)$ and thus it has size $rq^6(q^6 - 1)/(q^2 - 1)$ when $q$ is an $r$-th power of a prime [138, Proposition 4.6.7]. We also note that by [138, Corollary 3.5.7], the split Cayley hexagon $H(q)$ is isomorphic to its point-line dual $H(q)^D$ if and only if $q$ is a power of 3.

For every prime power $q$, we also have a generalized hexagon of order $(q^3, q)$ known as the twisted triality hexagon, which we denote by $T(q^3, q)$. Its point-line dual is denoted by $T(q, q^3)$. We do not give its definition here and refer the interested reader to [138, Chapter 2]. We have the following well known inclusion of geometries between the classes of generalized hexagons we have discussed so far:

$$H(q, 1) \subset H(q)^D \subset T(q, q^3).$$

Clearly this is a sequence of full isometrically embedded subgeometries.

The doubling construction can also be used to construct generalized octagons of order $(q, 1)$ from generalized quadrangles of order $(q, q)$. There is another class of generalized octagons known as the Ree-Tits octagons, which have order $(q, q^2)$, for $q$ an odd power of 2, and are denoted by $GO(q, q^2)$. For the definition of this geometry see [137]. If $q = 2^{2e+1}$, then $|\text{Aut}(GO(q, q^2))| = (2e + 1)q^{12}(q^6 + 1)(q^4 - 1)(q^3 + 1)(q - 1)$ (see [138, Proposition 4.6.10]).

### 1.2.2. Classification of Finite Generalized Polygons

One of the most important results in the theory of generalized polygons is the following theorem due to Feit and G. Higman [80] (also see [138, Theorem 1.7.1]).

**Theorem 1.2.7.** Let $S$ be a finite generalized $n$-gon, with $n \geq 3$, of order $(s, t)$. Then one of the following holds:

- $S$ is an ordinary $n$-gon, and thus $s = t = 1$. 

\begin{itemize}
\item $S$ is a non-degenerate projective plane of order $s = t \geq 2$.
\item $S$ is a generalized quadrangle and the number $st(1 + st)/(s + t)$ is an integer.
\item $S$ is a generalized hexagon; the number $st$ is a square if $s,t > 1$, and in that case the following numbers are integers for $u = \sqrt{st}$ and $w = s + t$,
\[
\frac{u^2(1 + w + u^2)(1 + u + u^2)}{2(w + u)}, \frac{u^2(1 + w + u^2)(1 - u + u^2)}{2(w - u)}.
\]
\item $S$ is a generalized octagon; the number $2st$ is a square if $s,t > 1$, and in that case the following numbers are integers for $u = \sqrt{\frac{st}{2}}$ and $w = s + t$,
\[
\frac{u^2(1 + w + 2u^2)(1 + 2u^2)(1 + 2u + 2u^2)}{2(w + 2u)}, \frac{u^2(1 + w + 2u^2)(1 + 2u^2)(1 - 2u + 2u^2)}{2(w - 2u)}.
\]
\item $S$ is a generalized dodecagon, and either $s = 1$ or $t = 1$.
\end{itemize}

For thick finite generalized polygons, Proposition 1.2.1 combined with Theorem 1.2.7 tells us that besides the projective planes, there are only generalized quadrangles, hexagons, and octagons. There are further restrictions on the parameters of these geometries due to Higman, Haemers and Roos [88,90,91].

**Theorem 1.2.8.** Let $S$ be a finite generalized $2n$-gon of order $(s,t)$ with $s,t,n \geq 2$. Then the following hold:
\begin{enumerate}
\item if $n = 2$, then $s \leq t^2$ and $t \leq s^2$;
\item if $n = 3$, then $s \leq t^3$ and $t \leq s^3$;
\item if $n = 4$, then $s \leq t^2$ and $t \leq s^2$.
\end{enumerate}

Even with all these restrictions, we are nowhere near a full classification of finite generalized polygons. There are infinitely many parameters which satisfy the conditions above but for which we have no idea about existence or non-existence of a generalized polygon with those parameters (see [63] Section 5.8 for a full list of parameters for which the existence is known). While there are many families of finite generalized quadrangles besides those coming from rank 2 polar spaces that we discussed in Section 1.2.1 (see [116] Chapter 3), the situation is quite different for generalized hexagons and octagons. The examples mentioned in Section 1.2.1 are the only known thick finite generalized hexagons and octagons. Moreover, even when there exists a generalized $n$-gon of a given order, we usually do not have a classification of all generalized $n$-gons of that order, except for some small cases. For example, it is not known whether $H(3)$ is the unique generalized hexagon of order 3.

For $s = 2$, a finite generalized quadrangle of order $(s,t)$ necessarily has $t \in \{1,2,4\}$ by the restrictions above, and for all these cases there is a unique generalized quadrangle of the given order. For $s = 3$, we have $t \in \{1,3,5,6,9\}$. There is no GQ of order $(3,6)$. For $t \in \{1,5,9\}$ there is a unique GQ. For $t = 3$ there are exactly two GQ’s, dual to each other. There is a unique GQ of order $(4,t)$ for $t \in \{1,2,4\}$, but the uniqueness is not known for orders $(4,6)$, $(4,8)$ and $(4,16)$ (existence of GQ’s of order $(4,11)$ and
(4, 12) is still unknown). See [116, Chapter 6] for the proofs of all these results and the relevant references. Again by the restrictions above, a finite generalized hexagon of order \((2, t)\) must have \(t \in \{1, 2, 8\}\). In [53], Cohen and Tits proved that \(H(2, 1), H(2), H(2)^D\) and \(T(2, 8)\) are the only finite generalized hexagons of order \((2, t)\). For \(s = 3\), we have \(t \in \{1, 3, 27\}\), and only for \(t = 1\) we know that the generalized hexagon is unique. For the case of generalized octagons, we do not even know if the smallest known thick generalized octagon, the Ree-Tits octagon of order \((2, 4)\), is the unique generalized octagon of order \((2, 4)\).

We finally note that the situation is not so hopeless if we assume some extra conditions on the generalized polygon. For example, using the classification of finite simple groups, Buekenhout and Van Maldeghem [40] have classified all finite generalized polygons whose automorphism group acts distance transitively on the set of points. There are several other interesting conditions that one can impose which give rise to some classification results, see for example [119] and [138, Chapters 4,5].

### 1.3. Near Polygons

Near polygons were introduced by Shult and Yanushka in 1980 [126] for studying the so-called tetrahedrally closed line systems in Euclidean spaces. They now form an important class of point-line geometries and have close connections to distance-regular graphs [34] and polar spaces [42]. The standard reference for near polygons is [58], which along with [63] will be our main reference for this section.

**Definition.** A near \(2n\)-gon, for \(n \in \mathbb{N}\), is a partial linear space \(S = (P, L, I)\) which satisfies the following axioms:

**NP1** the collinearity graph of \(S\) is connected with diameter \(n\);

**NP2** for every point \(x \in P\) and every line \(L \in L\), there exists a unique point \(\pi_L(x)\) incident with \(L\) that attains the minimum distance between \(x\) and points incident with \(L\).

A near polygon is a near \(2n\)-gon for some \(n \in \mathbb{N}\). A near 0-gon is just a point while a near 2-gon is a line. It is easy to see that every generalized \(2n\)-gon is also a near \(2n\)-gon. In fact, every generalized \(2n\)-gon is a special kind of near \(2n\)-gon, as the following result shows.

**Proposition 1.3.1** ([63, Theorem 5.14]). For an integer \(n \geq 2\), every near \(2n\)-gon \(S\) that satisfies the following conditions is a generalized \(2n\)-gon.

1. Every point of \(S\) is incident with at least two lines.
2. For every pair of points \(x, y\) at distance \(i \in \{1, 2, \ldots, n - 1\}\) in the collinearity graph of \(S\), there exists a unique point of \(S\) at distance \(i - 1\) from \(x\) and distance 1 from \(y\).

Looking at generalized \(2n\)-gons as special kinds of near \(2n\)-gons will be quite useful to us, and we will do so whenever convenient. If we remove Condition (1) in Proposition 1.3.1, then we get the so-called degenerate generalized polygons; for example, a set of lines through a common point gives rise to a degenerate generalized quadrangle.
A simple class of near polygons which are not generalized polygons is the class of Hamming near $2n$-gons, $n \geq 3$, defined as follows: for arbitrary nonempty sets $L_1, \ldots, L_n$, take $P = L_1 \times \cdots \times L_n$ and let $L$ to be the union of sets $L_i$’s, for $i \in \{1, \ldots, n\}$, where $L_i = \{\{x_1\} \times \cdots \times \{x_{i-1}\} \times L_i \times \{x_{i+1}\} \times \cdots \times \{x_n\} \mid x_j \in L_j$ for $j \in \{1, \ldots, n\} \setminus \{i\}\};$ then $(P, L)$ with incidence as set containment is a near $2n$-gon. Another example is the near $2n$-gon $H_n$ of order $(2, (\frac{n+1}{2}) - 1)$ obtained by taking the partitions of $\{1, \ldots, 2n+2\}$ into $n + 1$ pairs as points and partitions into $n - 1$ pairs and a 4-subset as lines, a point being incident with a line if it is a refinement of the line. When $n$ is equal to 2, this gives us the generalized quadrangle of Figure 1.1. For a proof of the fact that $H_n$ is a near $2n$-gon, see [58, Section 6.2]. There are also some near polygons related to sporadic finite simple groups. For example, the near hexagon $E_2$ of order $(2, 14)$ related to the Mathieu group $M_{24}$, which is constructed by taking the 759 blocks of the Witt design $S(5,8,24)$ as points and triples of pairwise disjoint blocks as lines (see [58, Chapter 6] for more on this near polygon). We will later encounter the Hall-Janko near octagon $HJ$ related to the Hall-Janko group $J_2$ (see [30,52] for its definition and properties).

Since a near polygon does not have any ordinary triangles as subgeometries, the maximal cliques of its collinearity graph correspond bijectively to the lines of the near polygon. This leads to the following result on isomorphisms between near polygons.

**Lemma 1.3.2** ([63, Theorem 6.2]). If $S_1$ and $S_2$ are two near polygons with collinearity graphs $\Gamma_1$ and $\Gamma_2$, respectively, then $S_1$ is isomorphic to $S_2$ if and only if $\Gamma_1$ is isomorphic to $\Gamma_2$.

For near polygons that have an order, we have the following easy but rather useful result.

**Lemma 1.3.3** ([58, Theorem 1.2]). Let $S = (P, L, I)$ be a finite near polygon of order $(s,t)$ and let $x$ be a point of $S$. Then

$$\sum_{y \in P} \left( -1 \right)^{d(x,y)} = 0.$$

**Proof.** By NP2, for every line $L$ the sum $\sum_{y \in L} \left( -1 \right)^{d(x,y)}$ is 0. Therefore, we have

$$0 = \sum_{L \in \mathcal{L}} \sum_{y \in L} \left( -1 \right)^{d(x,y)} = \sum_{y \in P} \sum_{L \in \mathcal{L}} \left( -1 \right)^{d(x,y)} = (t + 1) \sum_{y \in P} \left( -1 \right)^{d(x,y)}.$$

**Definition.** A regular near $2n$-gon is a near $2n$-gon $S$ with an order $(s,t)$ and constants $t_i$, for $i \in \{0, \ldots, n\}$, such that for every two points $x$ and $y$ of $S$ at distance $i$ from each other, there are precisely $t_i + 1$ lines through $y$ containing a point at distance $i - 1$ from $x$. Clearly, $t_0 = -1$, $t_1 = 0$ and $t_n = t$. We say that $S$ is regular with parameters $(s,t; t_2, \ldots, t_{n-1})$.

**Lemma 1.3.4** ([58, Theorem 1.25]). The regular near $2n$-gons, $n \geq 1$, are precisely those near $2n$-gons whose collinearity graph is distance regular.

For the definition and properties of distance regular graphs, we refer to [34]. We note that the Hall-Janko near octagon is a regular near octagon of parameters $(2,4;0,3)$ and...
in fact Cohen and Tits proved that it is the unique regular near octagon with these parameters \[53\]. It is also well-known that the Hall-Janko near octagon contains the generalized hexagon \(H(2)\) as a subgeometry. Note that generalized 2n-gons with an order \((s, t)\) are precisely the regular near 2n-gons with parameters \((s, t; 0, \ldots, 0)\). Just like the case of generalized polygons, elementary counting gives us the following result for regular near polygons.

**Lemma 1.3.5** (\[58\] Chapter 3). Let \(S\) be a near 2n-gon with parameters \(s, t, t_i\) with \(i \in \{0, \ldots, n\}\). Let \(x\) be a point of \(S\) and \(\Gamma\) the collinearity graph of \(S\). Then the number \(|\Gamma_i(x)|\), for \(i \in \{0, \ldots, n\}\) is independent from the chosen point \(x\) and is equal to

\[
k_i = \frac{s^i \prod_{j=0}^{i-1} (t - t_j)}{\prod_{j=1}^i (t_j + 1)},
\]

and the total number of points in \(S\) is equal to \(v = k_0 + \cdots + k_n\).

We include another characterization of generalized 2n-gons in terms of near 2n-gons. Recall that the number of points in a generalized 2n-gon of order \((s, t)\) is equal to \((1 + s)(1 + st + s^2t^2 + \cdots + s^{n-1}t^{n-1})\) (see Proposition 1.2.4).

**Lemma 1.3.6.** Let \(S = (\mathcal{P}, \mathcal{L}, I)\) be a near 2n-gon, \(n \geq 2\), of order \((s, t)\). Then we have

\[
|\mathcal{P}| \leq (1 + s)(1 + st + s^2t^2 + \cdots + s^{n-1}t^{n-1}),
\]

with equality if and only if \(S\) is a generalized 2n-gon.

**Proof.** Let \(x\) be a point of \(S\) and denote the set of points at distance \(i\) from \(x\) by \(\Gamma_i(x)\). By NP2, for every \(i \in \{1, \ldots, n\}\) there is no line completely contained in \(\Gamma_i(x)\). Since there are \(t + 1\) lines through \(x\), each containing \(s\) points besides \(x\), we have \(|\Gamma_1(x)| = s(t + 1)|. Similarly, every point of \(\Gamma_1(x)\) is collinear with exactly \(st\) points of \(\Gamma_2(x)\), and every point of \(\Gamma_2(x)\) is collinear with at least one point of \(\Gamma_1(x)\). Therefore, we have \(|\Gamma_2(x)| \leq st|\Gamma_1(x)| = s^2t(t + 1)|. Similarly for each \(i \in \{2, \ldots, n - 1\}\) we get \(|\Gamma_i(x)| \leq st|\Gamma_{i-1}(x)|\), and \(|\Gamma_n(x)| \leq st|\Gamma_{n-1}(x)|/ (t + 1)|. From all these inequalities we can see that

\[
|\mathcal{P}| \leq 1 + \sum_{i=1}^{n-1} s^i t^{i-1}(t + 1) + s^nt^{n-1} = (1 + s)(1 + st + s^2t^2 + \cdots + s^{n-1}t^{n-1}),
\]

with equality if and only if equality occurs at each “level”, which is equivalent to \(S\) being a regular near polygon of parameters \((s, t; 0, \ldots, 0)\), i.e., a generalized 2n-gon. \(\square\)

### 1.3.1. Substructures of a Near Polygon

One of the most fundamental structural results for near polygons is the existence of certain substructures called **quads**, which is going to be crucial in many of our proofs later. This result was proved by Shult and Yanushka in \[126\] and later generalized by Brouwer and Wilbrink in \[38\] to include existence of sub near polygons of larger diameter. We mention the main results regarding quads and convex subspaces that we will need and refer the reader to \[58\] for more details.
A subset $X$ of points in a partial linear space $S = (P, L, I)$ is called a \textit{subspace} if for every pair of distinct collinear points in $X$, all the points of the line joining these points are contained in $X$. A subspace is called \textit{convex} if for every pair of points $x, y \in X$, every point on every shortest path between $x$ and $y$ in the collinearity graph is contained in $X$. It is easy to see that every subset $X$ of points of a partial linear space $S = (P, L, I)$ is contained in a unique smallest convex subspace $C(X)$. For every nonempty convex subspace $X$ of $S$, we can define a full isometrically embedded subgeometry of $S$ by taking the elements of $X$ as the points of the subgeometry and all the lines $L$ whose every point is contained in $X$ as the lines of the subgeometry. We call this subgeometry, the \textit{subgeometry induced by} $X$. We begin with the simplest non-trivial convex subspaces, the lines.

\textbf{Lemma 1.3.7 (\cite{38} Lemma 1).} Let $L_1, L_2$ be two lines of a near polygon $S$. Then one of the following two cases occurs:

1. There exists a point $y_1 \in L_1$ and a point $y_2 \in L_2$ such that $d(L_1, L_2) = d(y_1, y_2)$ and for every $x_1 \in L_1$ and $x_2 \in L_2$, we have $d(x_1, x_2) = d(x_1, y_1) + d(y_1, y_2) + d(y_2, x_2)$.

2. For every point $x_1 \in L_1$, there exists a unique point $x_2 \in L_2$ such that $d(x_1, x_2) = d(L_1, L_2)$, and for every point $y_2 \in L_2$, there exists a unique point $y_1 \in L_1$ such that $d(y_1, y_2) = d(L_1, L_2)$. In this case we say that the lines $L_1$ and $L_2$ are parallel.\footnote{Note that parallelism is not a transitive relation here.}

\textbf{Definition.} A \textit{quad} $Q$ of a near polygon $S$ is a convex subspace of $S$ that induces a subgeometry isomorphic to a (non-degenerate) generalized quadrangle.

The following result of Shult and Yanushka on existence of quads in a near polygon will be used implicitly in our arguments later.

\textbf{Theorem 1.3.8 (\cite{126} Proposition 2.5).} Let $a, b$ be two points of a near polygon $S$ at distance 2 from each other with more than one common neighbor. Let $c, d$ be two common neighbors of $a$ and $b$. If at least one of the lines $ac, ad, bc, bd$ contains at least three points, then $a$ and $b$ are contained in a unique quad of $S$.

Most of the near polygons studied in this thesis will have three points on each line, for which Theorem 1.3.8 says that every two points at distance 2 from each other which have more than one common neighbor have a unique quad through them. This quad is a generalized quadrangle of order $(2, t)$ for some possibly infinite cardinal number $t$. It was proved by Cameron in \cite{41} that for every generalized quadrangle of order $(2, t)$, the parameter $t$ must be finite. Thus by Theorems 1.2.7 and 1.2.8 we must have $t \in \{1, 2, 4\}$. In view of Theorem 1.3.8 this implies the following useful lemma.

\textbf{Lemma 1.3.9.} If $S$ is a (possibly infinite) near polygon with three points on each line, then every two points of $S$ at distance 2 from each other have either 1, 2, 3 or 5 common neighbors.

It is not difficult to classify all finite generalized quadrangles of order $(2, t)$ (see for example \cite{58} Section 1.10]). For $t = 1$ we have the $(3 \times 3)$-grid. The remaining cases, $t = 2$ and $t = 4$ give us $W(2)$ (see Figure 1.1) and $Q(5, 2)$ (see \cite{116} Section 3.1] for its definition), respectively. The corresponding quads of a near polygon with three points on each line will be called grid-quads, $W(2)$-quads and $Q(5, 2)$-quads, respectively. We will also need the following property of quads which is a direct consequence of Theorem 1.3.8.
Lemma 1.3.10. Let \( L_1, L_2 \) be two intersecting lines of a near polygon \( S \). Then there is at most one quad of \( S \) which contains both \( L_1 \) and \( L_2 \).

Let \( x \) be a point of a near polygon \( S \) and \( F \) a convex subspace of \( S \) (for example, a quad or a line). Then we say that the point \( x \) is classical with respect to \( F \), if there exists a (necessarily unique) point \( \pi_F(x) \in F \) such that \( d(x, y) = d(x, \pi_F(x)) + d(\pi_F(x), y) \) for every \( y \in F \). The point \( \pi_F(x) \) is called the projection of \( x \) on \( F \). It follows from NP2, that every point is classical with respect to a given line. We call a convex subspace \( F \) of \( S \) classical if every point of \( S \) is classical with respect to \( F \). This notion of classical subspaces will be studied in a much more general setting in Chapter 2. Cameron proved in \[42\] that every near polygon in which every pair of points at distance 2 have a unique quad through them and every quad is classical must be a dual polar space.

Lemma 1.3.11 (\[63\], Theorem 6.8]). Let \( F \) be a nonempty convex subspace of a near polygon \( S \) and let \( x \) be a point of \( S \) such that \( d(x, F) \leq 1 \). Then \( x \) is classical with respect to \( F \).

Lemma 1.3.12 (\[63\], Theorem 6.9]). The intersection of two classical convex subspaces \( F_1, F_2 \) of a near polygon \( S \) is either empty or a classical convex subspace.

1.3.2. Near Hexagons of Order 2

In this section we apply the basic theory of near polygons mentioned so far, along with some well-known results, to classify all near hexagons of order 2. This result fits better in Chapter 6 where – among other things – we prove that the dual split Cayley hexagon \( H(2)^D \) is the unique near hexagon of order \((2, 2)\) which contains the generalized hexagon \( H(2, 1) \) as a full isometrically embedded subgeometry. But due to its elementary nature we prove the result here.

Both the split Cayley hexagon \( H(2) \) and its dual \( H(2)^D \) are examples of near hexagons of order 2. Another example is the Hamming near hexagon \( L_3 \times L_3 \times L_3 \) where \( L_3 \) is just a set (line) of three elements (points). We will show that there are no more near hexagons of order 2. Note that in a generalized hexagon of order 2 every pair of points at distance 2 have a unique common neighbor, while in the Hamming near hexagon of order 2 every pair of points at distance 2 from each other have exactly 2 common neighbors.

Lemma 1.3.13. Let \( S \) be a finite near hexagon of order \((s, t)\) and \( Q \) a quad of \( S \) that has order \((s, t')\). Then \( t' < t \).

Proof. We know that \( t' \leq t \). For the sake of contradiction, assume that \( t' = t \). Let \( x \) be a point of \( Q \). Since \( t = t' \), all lines of \( S \) through \( x \) are already contained in \( Q \), and thus \( x \) cannot be collinear with any point that is not contained in \( Q \). But then, there cannot be any points of \( S \) that lie outside \( Q \), as the collinearity graph of \( S \) is connected. Thus \( S = Q \), which is a contradiction.

Lemma 1.3.14. Let \( S \) be a near hexagon of order 2. Then the number of common neighbors of a pair of points at distance 2 from each other is a constant \( k \in \{1, 2\} \).
Proof. Let \( v \) denote the total number of points of \( S \). For a fixed point \( x \) let \( n_i(x) \) denote the number of points at distance \( i \in \{0, 1, 2, 3\} \) from \( x \) (in the collinearity graph). For all \( x \in \mathcal{P} \), we have \( n_0(x) = 1 \), \( n_1(x) = 6 \), and thus
\[
n_2(x) + n_3(x) = v - 7. \tag{1.1}
\]
By Lemma 1.3.3 we have
\[
n_0(x) - \frac{n_1(x)}{2} + \frac{n_2(x)}{4} - \frac{n_3(x)}{8} = 0. \tag{1.2}
\]
Solving equations (1.1) and (1.2) we get that \( n_2(x) = \frac{(v + 9)}{3} \) and \( n_3(x) = \frac{(2v - 30)}{3} \) for all \( x \in \mathcal{P} \). Therefore these numbers only depend on \( v \), and we can define constants
\[
n_0 = 1, n_1 = 6, n_2 = \frac{(v + 9)}{3} , n_3 = \frac{(2v - 30)}{3}. \tag{1.3}
\]
By Lemma 1.3.13 all quads of \( N \) are grid-quads. For a point \( x \), let \( N(x) \) be the number of grid-quads that contain \( x \). Then the number of points at distance 2 from \( x \) that are contained in a grid along with \( x \) is equal to \( 4N(x) \) since there is a unique quad through a pair of points at distance 2 which have more than one common neighbor by Theorem 1.3.8.

Double counting edges between \( \Gamma_1(x) \) and \( \Gamma_2(x) \) we get that
\[
2 \cdot 4N(x) + 1 \cdot (n_2 - 4N(x)) = n_1 \cdot 4, \quad \text{and hence } N(x) = \frac{(63 - v)}{12}. \tag{1.4}
\]
So, the total number of grid-quads through a point is a constant given by \( N := \frac{(63 - v)}{12} \).

By Lemma 1.3.10, we must have \( N \in \{0, 1, 2, 3\} \) as there are only 3 lines through a point. Since \( v = 63 - 12N \), using double counting we get that the total number of grid-quads in \( N \) is
\[
N(63 - 12N)/9.
\]
This number is not an integer if \( N \in \{1, 2\} \). Therefore, \( N \) must be 0 or 3. If \( N \) is 0, then there are no quads, and hence every two points at distance 2 from each other have a unique common neighbor. Say \( N \) is equal to 3 and let \( x, y \) be a pair of points at distance 2 from each other. Every line through \( x \) is contained in precisely two of the three grid-quads through \( x \). Thus for every neighbor \( z \) of \( x \), the two lines through \( z \) that contain a point of \( \Gamma_2(x) \) are contained in grids through \( x \). This implies that there is a grid through \( x \) and \( y \), i.e., the number of common neighbors between \( x \) and \( y \) is 2.

Now let \( S \) be a near hexagon of order 2 and let \( k \in \{1, 2\} \) be the constant which is equal to the number of common neighbors between any pair of points at distance 2 from each other in \( S \). If \( k = 1 \), then it follows from Proposition 1.3.1 that \( S \) is a generalized hexagon, and hence by the classification result of Cohen and Tits it is either isomorphic to \( H(2) \) or \( H(2)^D \). So, suppose that \( k = 2 \). Then we can either use the classification result of Brouwer et al. \cite{53} (see number (xi) in Theorem 1.1 of the paper) or simply draw some pictures and convince ourselves that \( S \) must be isomorphic to \( L_3 \times L_3 \times L_3 \).

Remark. The classification of finite near polygons is much harder than the classification of finite generalized polygons. But some success has been achieved for certain classes of near polygons, like the dense near hexagons and octagons with \( k \in \{3, 4\} \) points on each line (see \cite{58}).
2. Valuations of Near Polygons

2.1. Introduction

Consider the following problem:

Given a near polygon $S$, determine all near polygons which contains an isomorphic copy of $S$ as a full subgeometry.

One of the most fruitful tools to tackle this problem has been the theory of valuations, introduced by De Bruyn and Vandecasteele in [64], where one computes certain integer valued functions on the point set of a near polygon $S$ satisfying some well chosen axioms and then uses them to determine how near polygons containing $S$ as a full subgeometry look like. For example, De Bruyn and Vandecasteele used this theory to classify certain classes of dense near polygons, i.e., near polygons in which every two points at distance 2 have more than one common neighbor, by exploiting the fact that dense near $2n$-gons contain convex subspaces which induce near $2m$-gons, for every $m \in \{2, \ldots, n-1\}$ [65] (also see [58] Chapters 6–9). Another important example is the use of valuations, satisfying a different set of axioms than before, by De Bruyn in [62] to prove that the Ree-Tits octagon of order $(2, 4)$ is the unique generalized octagon of order $(2, 4)$ containing a suboctagon of order $(2, 1)$. In fact, a similar result of De Medts and Van Maldegehem [67] on uniqueness of H(3) as a generalized hexagon of order 3 containing a subhexagon of order $(3, 1)$ can also be proved using this theory of valuations. For a survey on the various applications of valuations of a near polygon, see [61].

We now define and study the notion of valuations which will be used in this thesis. The basic definitions and results of this chapter will be used in Chapter 4 to prove non-existence of certain semi-finite generalized hexagons and in Chapter 6 to obtain characterizations of certain Suzuki tower near polygons. Almost all of these results on valuations are already implicit in the literature (for example, in [59 Section 2]), but for the ease of the reader we provide proofs.

2.2. Definitions and Properties

Definition. Let $S = (\mathcal{P}, \mathcal{L}, I)$ be a near $2n$-gon. A function $f : \mathcal{P} \to \mathbb{Z}$ is called a semi-valuation of $S$ if for every line $L \in \mathcal{L}$, there exists a unique point $x_L$ incident with $L$ such that $f(x) = f(x_L) + 1$ for every $x \neq x_L$ incident with $L$. A valuation of $S$ is a semi-valuation which attains a minimum value of 0. Two valuations $f, g$ of $S$ are called isomorphic if there exists an automorphism $\theta$ of $S$ such that $f(x) = g(\theta(x))$ for all $x \in \mathcal{P}.$
It directly follows from the definition that given a valuation \( f \) of a near polygon \( S \) and a point \( x \) with \( f \)-value 0, the points at distance \( i \) from \( x \) have \( f \)-value at most \( i \). Thus, the values taken by a valuation of a near \( 2n \)-gon lie in the set \( \{0, 1, \ldots, n\} \). If \( f \) is a valuation of a near \( 2n \)-gon \( S \), then we denote by \( O_f \) the set of points of \( S \) which have \( f \)-value 0, and by \( M_f \) the maximum value that \( f \) attains.

**Definition.** A hyperplane of a partial linear space \( S \) is a proper subset \( H \) of the set of points of \( S \) with the property that every line of \( S \) is either contained in \( H \) or intersects \( H \) in a unique point\(^1\). If a hyperplane does not contain any line of \( S \), then it is called a 1-ovoid of \( S \).

For a valuation \( f \) of a near polygon \( S = (P, L, I) \), let \( H_f \) be the set \( \{x \in P \mid f(x) < M_f\} \). For every line \( L \), there exists a point \( x_L \) on \( L \) such that \( f(x_L) = f(x) - 1 \) for all \( x \in L \setminus \{x_L\} \) and thus \( f(x_L) \leq M_f - 1 < M_f \). Therefore, the point \( x_L \) belongs to \( H_f \). Now say there are two points \( x \) and \( y \) on \( L \) which are contained in \( H_f \). Without loss of generality, let \( y \) be distinct from the unique point \( x_L \). Then every point of \( L \) has \( f \)-value at most \( f(y) \), which is less than \( M_f \) since \( y \) is in \( H_f \). Thus all the points of the line \( L \) are contained in \( H_f \). We have just proved that for every valuation \( f \) of \( S \) (in fact, one can take a semi-valuation), there is a corresponding hyperplane \( H_f \) of \( S \) consisting of those points of \( S \) that have non-maximal \( f \)-value. This correspondence between valuations and hyperplanes of \( S \) will be crucial in many of our results. We note that it is possible for two distinct valuations to give rise to the same hyperplane. A hyperplane \( H \) will be called of valuation type if there exists a valuation \( f \) such that \( H = H_f \). We now give some standard examples of valuations.

**Example.** Let \( S = (P, L, I) \) be a near \( 2n \)-gon, for some positive integer \( n \geq 2 \), such that \( \Gamma_n(x) \neq \emptyset \) for every point \( x \).

1. Let \( x \) be a fixed point of \( S \). Define \( f_x(y) = d(x, y) \) for all \( y \in P \). Then the function \( f_x \) is a valuation of \( S \), which is known as a classical valuation of \( S \). Its hyperplane \( H_{f_x} \) is the set of points at distance at most \( n - 1 \) from \( x \), and such a hyperplane will be called the singular hyperplane with center \( x \).

2. Let \( O \) be a 1-ovoid of \( S \). Define a function \( f_O : P \to \mathbb{Z} \) by \( f_O(x) = 0 \) if \( x \in O \) and \( f_O(x) = 1 \) if \( x \notin O \). Then \( f_O \) is a valuation of \( S \), which is known as an ovoidal valuation, and its associated hyperplane is equal to \( O \).

3. Suppose \( n \geq 3 \). Let \( x \) be a fixed point of \( S \) and let \( O' \) be a 1-ovoid of the subgeometry of \( S \) induced on the set \( \Gamma_n(x) \) of points at distance \( n \) from \( x \). Define \( f_{x,O'}(y) := d(x, y) \) for all points \( y \) at distance at most \( n - 1 \) from \( x \), \( f_{x,O'}(y) = n - 2 \) for \( y \in O' \) and \( f_{x,O'}(y) = n - 1 \) for all the remaining points of \( S \). Then \( f_{x,O'} \) is a valuation of \( S \), which is known as a semi-classical valuation. The associated hyperplane of \( f_{x,O'} \) is equal to \( O' \cup \Gamma \leq n-1(x) \), and this will be called a semi-singular hyperplane with center \( x \).

We will now show that in a generalized quadrangle which is not a dual grid (recall the definition from Section 1.2), every valuation is either classical or ovoidal. This will later

\(^1\)This definition is motivated by the same property of hyperplanes in projective spaces, and in fact when we embed a partial linear space in a projective space as a full subgeometry, the hyperplanes of the projective space give rise to the hyperplanes of the partial linear space [63, Section 4.5].
be used to derive the point-quad relationships in near polygons, as originally obtained by Shult and Yanushka in [126, Proposition 2.6].

Lemma 2.2.1. Let $S$ be a generalized quadrangle which is not a dual grid and let $x$ be a point of $S$. Then the subgraph of the collinearity graph $\Gamma$ induced on the set $\Gamma_2(x)$ of points at distance 2 from $x$ is connected and has diameter at most 3.

Proof. If $S$ is a grid then $\Gamma_2(x)$ is either a subline, or another grid and thus the graph has diameter at most 2. So assume that $S$ is neither a grid, nor a dual grid. Then by Proposition 1.2.3, $S$ has an order $(s,t)$. If $t = 1$ or $s = 1$, then $S$ is a grid or a dual grid. Therefore $s,t \geq 2$, and in particular every line of $S$ has at least three points.

Now let $x_1, x_2$ be two non-collinear points of $\Gamma_2(x)$. Then $d(x_1, x_2) = 2$ in $S$. Say, there exists a common neighbor of $x_1$ and $x_2$ which also lies in $\Gamma_2(x)$. Then $x_1, x_2$ have distance 2 in the graph induced on $\Gamma_2(x)$. Therefore, assume that all common neighbors of $x_1$ and $x_2$ lie in $\Gamma_1(x)$. Let $y_1, y_2$ be two such common neighbors. Since every line has at least three points, we can pick a point $y'_1$ on the line $x_1y_1$ which is not equal to $x_1$ or $y_1$. Then $y'_1$ must lie in $\Gamma_2(x)$. Clearly $y'_1$ is not collinear with either $x_2$ or $y_2$ as that would contradict the axiom $\text{GQ2}$ (see Figure 2.1). Let $y'_2$ be the unique point of the line $x_2y_2$ which is collinear with $y'_1$. Then $y'_2$ is also contained in $\Gamma_2(x)$, which gives us the path $x_1, y'_1, y'_2, x_2$ between $x_1$ and $x_2$ of length 3. Therefore, the graph is connected with diameter at most 3. \qed

Theorem 2.2.2. Let $S$ be a generalized quadrangle which is not a dual grid. Then every valuation of $S$ is either classical or ovoidal.

Proof. Let $f$ be a valuation of $S$. If $M_f = 1$, then every line contains a unique point of value 0, and hence $O_f$ is a 1-ovoid and $f$ is ovoidal. So, assume that $M_f = 2$. We will show that $f$ is classical. Let $x \in O_f$ and let $y$ be a point with $f$-value 2. Then every point in $\Gamma_1(x)$ has $f$-value 1. Let $y'$ be a point of $\Gamma_2(x)$ which is collinear with $y$, and let $y''$ be the unique point on the line $yy'$ which is collinear with $x$. Then $f(y'') = 1$, $f(y) = 2$, and therefore $f(y')$ must be equal to 2 by the property of valuations. Now by Lemma 2.2.1 every point in $\Gamma_2(x)$ has $f$-value 2. This shows that $f$ is a classical valuation with $x$ as the unique point with $f$-value 0. \qed

\[\text{The proof using valuations is essentially the same as the proof of Shult and Yanushka.}\]

\[\text{The case where } \Gamma_2(x) \text{ is a singleton is not possible as then } S \text{ must be a } 2 \times 2 \text{ grid, which contradicts the fact that } S \text{ is not a dual grid since a } 2 \times 2 \text{ grid is also a dual grid.}\]
Recall the main problem stated in Section 2.1. We will now see why valuations can be useful in tackling that problem.

**Theorem 2.2.3.** Let $S = (P, \mathcal{L}, 1)$ be a near polygon which is a full subgeometry of another near polygon $S' = (P', \mathcal{L}', 1')$. Then for every point $x$ in $P'$, the function $f_x : P \rightarrow \mathbb{Z}$ defined by $f_x(y) = d(x, y) - d(x, P)$ is a valuation of $S$. Moreover, if $S$ is isometrically embedded, then for every $x \in P$ the valuation $f_x$ is a classical valuation of $S$.

**Proof.** Let $L \in \mathcal{L}$ be a line of $S$, and let $x_L = \pi_L(x)$ be the unique point on $L$ which is nearest to $x$ in $S'$. Since $S$ is a full subgeometry, $x_L \in P$. Then for every point $y$ on $L$, we have $d(x, y) = d(x, x_L) + 1$, and hence $x_L$ is the unique point on $L$ with minimum $f_x$-value. Taking a point $y \in P$ with $d(x, y) = d(x, P)$, we see that $f_x$ attains the value 0. Thus, $f_x$ is a valuation of $S$.

Now assume that $S$ is isometrically embedded and let $x \in P$. Then for every $y \in P$ we have $f_x(y) = d(x, y) = d_S(x, y)$, and hence $f_x$ is classical with center $x$. □

In view of Theorem 2.2.3 whenever we have a near polygon $S = (P, \mathcal{L}, 1)$ as a full subgeometry of another near polygon $S' = (P', \mathcal{L}', 1')$ and $x$ is a point of $S'$, then $f_x$ will denote the valuation of $S$ defined by $f_x(y) = d(x, y) - d(x, P)$ for $y \in P$. This will sometimes be referred as the valuation of $S$ corresponding to the point $x$ of $S'$.

**Lemma 2.2.4.** Let $S = (P, \mathcal{L}, 1)$ be a near polygon which is a full subgeometry of a near $2n$-gon $S' = (P', \mathcal{L}', 1')$. For every $x \in P'$, let $f_x$ be the corresponding valuation of $S$. Then we have the following:

1. If $d(x, P) \geq i$, then $M_{f_x} \leq n - i$.

2. If $d(x, P) = 1$ and $|O_{f_x}| = 1$, then $x$ is collinear with a unique point of $S$.

**Proof.** For a point $x \in P'$, the maximum possible distance between $x$ and a point of $P$ is $n$. Since $f_x(y) = d(x, y) - d(x, P) \leq n - i$ for every $y \in P$, we have $M_{f_x} \leq n - i$. If $d(x, P) = 1$, then the set $O_{f_x}$ corresponds to the points of $S$ which are at distance 1 from $x$. □

Theorem 2.2.3 shows that if we are given a near polygon $S$, and if we can somehow determine the set $V$ of all possible valuations of $S$, then given any near polygon $S'$ containing $S$ as a full subgeometry, to each point of $S'$ we can associate an element of $V$. This mapping is usually neither injective, nor surjective. But in some cases — as we will see later — we can reconstruct $S'$ using some well chosen elements of $V$ (which we have already computed). But first, we derive the well-known point-quad relations in a near polygon. Given a quad $Q$ of a near polygon $S$, recall that we call a point $x$ classical with respect to $Q$ if there exists a point $\pi_Q(x) \in Q$ such that for every $y \in Q$ we have $d(x, y) = d(x, \pi_Q(x)) + d(\pi_Q(x), y)$. We call a point ovoidal with respect to $Q$ if the set of points in $Q$ which are at distance $d(x, Q)$ from $x$, i.e., points of $Q$ which are nearest to $x$, form a 1-void of $Q$.

**Theorem 2.2.5.** Let $x$ be a point and $Q$ a quad of a near polygon $S$ such that $Q$ is not a dual grid. Then either $x$ is classical with respect to $Q$ or $x$ is ovoidal with respect to $Q$.

**Proof.** This is an immediate corollary of Theorems 2.2.2 and 2.2.3 as $d(x, y) = f_x(y) + d(x, Q)$ for every $y \in Q$. □

\footnote{Note that we do not make the assumption that these near polygons have the same diameter.}
For a near polygon $S$, we have associated points of an arbitrary near polygon $S'$ containing $S$ as a full subgeometry to elements of the set $V$ of all valuations of $S$. Of course, it will help if we can associate lines of $S'$ to certain subsets of $V$. This motivates the following definition.

**Definition.** Let $f, g$ be two valuations of a near polygon $S$. Then we say that $f$ and $g$ are *neighboring* valuations if there exists an integer $\epsilon$ such that $|f(x) - g(x) + \epsilon| \leq 1$ for every point $x$ of $S$.

Note that the integer $\epsilon$ defined above must belong to the set $\{-1, 0, 1\}$. This can be shown as follows. If $\epsilon \leq -2$, then for a point $x$ in $\mathcal{O}_f$ we have $f(x) - g(x) + \epsilon = 0 - g(x) + \epsilon \leq -2$ since $g(x) \geq 0$, which is a contradiction to the fact that $|0 - g(x) + \epsilon| \leq 1$. Therefore $\epsilon \geq -1$. Similarly, if $\epsilon \geq 2$, then for a point $y$ in $\mathcal{O}_g$ we have $f(y) - g(y) + \epsilon = f(y) - 0 + \epsilon \geq 2$ since $f(y) \geq 0$, which is again a contradiction as $|f(y) - 0 + \epsilon| \leq 1$. Therefore, $\epsilon \leq 1$. Moreover, the number $\epsilon$ is uniquely determined by $f$ and $g$ unless $f = g$, in which case $\epsilon$ can be taken to be any number in $\{-1, 0, 1\}$ (see for example [59, Corollary 2.3]).

**Theorem 2.2.6.** Let $S = (\mathcal{P}, \mathcal{L}, I)$ be a near polygon which is a full subgeometry of another near polygon $S' = (\mathcal{P}', \mathcal{L}', V')$. Then for every line $L$ of $\mathcal{L}'$, $\{f_x \mid x \in V' \cap L\}$ is a set of pairwise neighboring valuations of $S$.

**Proof.** Let $L$ be a line of $\mathcal{L}'$, and $x, y$ two points on $L$. Then for every point $z \in \mathcal{P}$, we have $|d(z, x) - d(z, y)| \leq 1$ by the triangle inequality. Now write $d(z, x) = f_x(z) + d(x, \mathcal{P})$, $d(z, y) = f_y(z) + d(y, \mathcal{P})$ and $\epsilon = d(x, \mathcal{P}) - d(y, \mathcal{P})$. Then for every $z \in \mathcal{P}$, we have $|f_x(z) - f_y(z) + \epsilon| \leq 1$, which shows that $f_x$ and $f_y$ are neighboring valuations.

\[\square\]

### 2.3. Three Points on Each Line

We now restrict to the case when the near polygons have three points on each line, i.e., we have a near polygon $S$ contained in another near polygon $S'$ as a full subgeometry and every line of $S'$ is incident with exactly three points. Then by applying Theorems 2.2.3 and 2.2.6 to the points of $S'$ we can associate valuations of $S$ and to the lines of $S'$ we can associate triples of pairwise neighboring valuations of $S$. We will show that it suffices to focus on triples of distinct valuations and see how all the information regarding valuations can be written in a “compact form”. All the results of this section are essentially contained in [59]. But there the notation used is different and the results proved are slightly more general. Therefore, it is worthwhile to revisit the proofs.

Let $S = (\mathcal{P}, \mathcal{L}, I)$ be a near polygon with three points on each line. Let $f_1$ and $f_2$ be two neighboring valuations of $S$ and let $\epsilon \in \{-1, 0, 1\}$ be such that $|f_1(x) - f_2(x) + \epsilon| \leq 1$ for all $x \in \mathcal{P}$. We define a function $f_3^*: \mathcal{P} \rightarrow \mathbb{Z}$ as follows. For a point $x \in \mathcal{P}$, if $f_1(x) = f_2(x) - \epsilon$, then we define $f_3^*(x) := f_1(x) - 1 = f_2(x) - \epsilon - 1$. For every other point $x$, we define $f_3^*(x) := \max\{f_1(x), f_2(x) - \epsilon\}$. Let $m$ (necessarily belonging to $\{-1, 0, 1\}$) be the minimum value taken by $f_3^*$, and define $f_3: \mathcal{P} \rightarrow \mathbb{N}$ as $f_3(x) := f_3^*(x) - m$ (so that $f_3$ attains the value 0). Then we denote this function $f_3$ by $f_1 * f_2$. Note that this function is well defined in the sense that if $f_1 = f_2$, then for any of the three possible values of $\epsilon$, we have $f_1 * f_2 = f_1 = f_2$. It also follows directly from the definition that $f_1 * f_2 = f_2 * f_1$.

**Lemma 2.3.1.** Let $f_1$ and $f_2$ be two neighboring valuations of a near polygon $S$ that has three points on each line. Let $f_3 = f_1 * f_2$. Then
(1) $f_3$ is also a valuation of $S$;
(2) $f_1, f_2$ and $f_3$ are all pairwise neighboring;
(3) we have $f_2 \ast f_3 = f_1$ and $f_1 \ast f_3 = f_2$.

**Proof.** (1) It suffices to show that the function $f'_3$ defined above is a semi-valuation. We show this under the weaker assumption that $f_1$ and $f_2$ are semi-valuations, and thus we can simply assume that $|f_1(x) - f_2(x)| \leq 1$ for all $x \in \mathcal{P}$ (every translate of a valuation is a semi-valuation and there is a unique translate of a semi-valuation which is a valuation).

Let $L$ be a line of $S$. For $i \in \{1, 2\}$, let $x_i$ be the unique point on $L$ such that $f_i(x) = f_i(x_i) + 1$ for all $x \in L \setminus \{x_i\}$. Say $x_1 = x_2$. Then for all $x \in L \setminus \{x_1\}$, we have $f_2(x) = f_2(x_2) + 1 = f_1(x_1) + c + 1 = f_1(x) + c$, where $c = f_2(x_1) - f_1(x_1)$. If $c = 0$, then $f'_2 = f_1 - 1$, and otherwise $f_3$ is either equal to $f_1$ or $f_2$ depending on the sign of $c$. Thus, in all these cases $f'_3$ is a semi-valuation.

Now say $x_1 \neq x_2$. If $f_1(x_1) > f_2(x_2)$, then $f_1(x_2) - f_2(x_2) = f_1(x_1) + 1 - f_2(x_1) \geq 2$, a contradiction. Similarly, we cannot have $f_1(x_1) < f_2(x_2)$ and therefore $f_1(x_1) = f_2(x_2) = a$. Let $x_3$ be the third point of $L$. Then $f'_3(x_1) = f'_3(x_2) = a + 1$ and $f'_3(x_3) = a$. Thus, $f'_3$ is a semi-valuation.

(2) We show that $f_1$ and $f_3$ are neighboring and the other cases follow from symmetry. Let $x$ be a point for which $f'_3(x) = f_1(x) - 1$. Since $f_3(x) = f_3(x) - m$, where $m$ is the minimum value of $f'_3$, we get $f_1(x) - f_3(x) + (-m) = 1$. Now let $x$ be any other point. Say $f_1(x) \geq f_3(x) - \epsilon$. Then $f_1(x) - f_3(x) + (-m) = 0$. Otherwise, $f_2(x) - \epsilon = f_3(x) + m$, but since $|f_1(x) - f_2(x) + \epsilon| \leq 1$, we get $|f_1(x) - f_3(x) + (-m)| \leq 1$. This shows that there exists an integer $-m$ such that $|f_1(x) - f_3(x) + (-m)| \leq 1$ for all $x$, which means that $f_1$ and $f_3$ are neighboring.

(3) Again, we will only prove that $f_1 \ast f_3 = f_2$. We have just seen that $f_1$ and $f_3$ are neighboring with $|f_1(x) - f_3(x) + (-m)| \leq 1$ for all $x \in \mathcal{P}$, where $m$ is the minimum value taken by the function $f'_3$ defined before. Define $f'$ as $f'(x) = f_1(x) - 1$ whenever $f_1(x) = f_3(x) - (-m)$ and $f'(x) = \max\{f_1(x), f_3(x) - (-m)\}$ otherwise. Note that $f_3(x) - (-m) = f'_3(x)$. Let $x$ be a point where $f_1(x) = f'_3(x)$. This only holds for $f_1(x) > f_2(x) - \epsilon$ and then $f'(x) = f_1(x) - 1 = f'_3(x) - 1$. Since $|f_1(x) - f_2(x) + \epsilon| < 1$, we must have $f_1(x) - 1 = f'_3(x) - 1 = f_2(x) - \epsilon$; thus $f'(x) = f_2(x) - \epsilon$.

Now let $x$ be a point where $f_1(x) \neq f'_3(x)$. Then we must have $f_2(x) - \epsilon \geq f_1(x)$. If there is equality, then $f'_3(x) = f_1(x) - 1$ and thus $f'(x) = f_1(x) + f'_3(x) = f_1(x) = f_2(x) - \epsilon$. If not, then $f_3(x) = f_2(x) - \epsilon > f_1(x)$, and hence $f'(x) = f_2(x) - \epsilon$. Therefore, $f'$ is just a translate of the valuation $f_2$ by $-\epsilon$, which implies that $f_1 \ast f_3 = f_2$.

The main addition to Theorems 2.2.3 and 2.2.6 for the case of three points per line is the following result, which leads us to the definition of Valuation Geometry of a near polygon with three points on each line.

**Theorem 2.3.2.** Let $S = (\mathcal{P}, \mathcal{L}, 1)$ be a near polygon that is a full subgeometry of another near polygon $S' = (\mathcal{P}', \mathcal{L}', 1')$ and suppose every line in $S'$ is incident with precisely three points. Let $\{x_1, x_2, x_3\}$ be a line of $S'$ and let $f_1, f_2, f_3$ be the valuations of $S$ induced by
the points \( x_1, x_2, x_3 \), respectively. Then (a) \( f_3 = f_1 \ast f_2 \); (b) if every point of the line is at the same distance from \( P \), then all three valuations are mutually distinct.

Proof. For each \( i \in \{1, 2, 3\} \), let \( d_i = d(x_i, P) \). We have seen that \( f_1 \) and \( f_2 \) are neighboring valuations with \( \epsilon = d_1 - d_2 \). Define \( f'_3 \) as before. We will show that \( f_3 \) is a translate of \( f'_3 \), and since there is only one possible translate of a semi-valuation which is a valuation this will show that \( f_3 = f_1 \ast f_2 \).

Let \( x \) be a point of \( S \). Say \( d(x, x_1) = d(x, x_2) \). This is equivalent to \( f_1(x) = f_2(x) + d_2 - d_1 = f_2(x) - \epsilon \). Then by NP2, we have \( d(x, x_1) = d(x, x_1) - 1 \), which in terms of valuations means \( f_3(x) + d_3 = f_1(x) + d_1 - 1 \). Therefore, \( f_3(x) = f_1(x) - 1 + \epsilon' \), where \( \epsilon' = d_1 - d_3 \). Now say \( d(x, x_1) \neq d(x, x_2) \). Then again by NP2, \( d(x, x_3) = \max\{d(x, x_1), d(x, x_2)\} \). In terms of valuations, we have \( f_3(x) + d_3 = \max\{f_1(x) + d_1, f_2(x) + d_2 = f_2(x) + d_2 - d_1 + d_1\} \), which is equivalent to \( f_3(x) = \max\{f_1(x) + \epsilon', f_2(x) - \epsilon + \epsilon'\} = \max\{f_1(x), f_2(x) - \epsilon\} + \epsilon' \). Therefore, \( f_3(x) = f'_3(x) + \epsilon' \) for all \( x \in P \) and hence \( f_3 = f_1 \ast f_2 \).

This shows that if any two of these valuations coincide, then all of them coincide. Therefore, it suffices to prove that we cannot have all of the valuations equal if \( d_1 = d_2 = d_3 \). Say \( f := f_1 = f_2 = f_3 \) and look at a point \( y \) in \( O_f \). Then we have \( d(x, y) = f_i(y) + d_i \) for each \( i \), which implies that \( d(x_1, y) = d(x_2, y) = d(x_3, y) \). This contradicts NP2. \( \square \)

Definition. Let \( S \) be a near polygon with three points on each line and let \( V \) be the set of all valuations of \( S \). Then the valuation geometry \( V \) of \( S \) is the partial linear space defined by taking the set \( V \) as the point set and the set of 3-element subsets \( \{f_1, f_2, f_3\} \) of pairwise distinct and neighboring valuations which satisfy \( f_3 = f_1 \ast f_2 \) as the line set.

Note that the valuation geometry of \( S \) does not directly give us any information about those lines of a near polygon \( S' \) containing \( S \) as a full subgeometry for which all three points on the line induce the same valuation. But in all of the cases considered in this thesis, we will show that no two collinear points of \( S' \) can induce the same valuation of \( S \), from which it will follow directly that each line of \( S' \) induces a line of the valuation geometry of \( S \).

We now see an example of how this valuation geometry can be useful, which will also be used to set up the notation for valuation geometries of near polygons. As a by product, we will get a proof of the uniqueness of the generalized quadrangle of order 2 using valuations. While this proof is in no way simpler than other proofs of uniqueness, it sets the template for more complicated arguments involving valuations that we will see in Chapters 4 and 6.

2.3.1. An Example – the Doily

For this section let \( S \) be the \((3 \times 3)\)-grid, i.e., the unique generalized quadrangle of order \((2,1)\)\footnote{Its uniqueness is quite easy to show using the GQ axioms.}. Then by Theorem 2.2.2 every valuation of \( S \) is either classical or ovoidal. From the transitivity of the automorphism group on the point set of \( S \), it follows that all classical valuations of \( S \) are isomorphic to each other. It is also easy to show that all ovoidal valuations of \( S \) are isomorphic. Let’s call the members of the isomorphism class of classical valuations as “type A” valuations, and the ovoidal ones as “type B” valuations.
(in general we will be giving labels to elements of an equivalence class of the valuation isomorphism). To every line of the valuation geometry $V$ of $S$, assign a type based on the types of the valuations it contains; which in this case is just a sorted string of A’s and B’s. For example, if in a line $\{f_1, f_2, f_3\}$, $f_1$ is classical and $f_2, f_3$ are ovoidal, then we will call the line to be of “type $ABB$”. Then the valuation geometry $V$, which can either be computed by hand or by the computer algorithms of Chapter [3], can be described by Tables [2.1] and [2.2]

Recall that for a valuation $f$, the maximum value of $f$ is denoted by $M_f$, the set of points with $f$-value 0 is denoted by $O_f$ and the hyperplane formed by the set of points that have $f$-value less than $M_f$ is denoted by $H_f$. The column “Value Distribution” in Table [2.1] contains arrays whose $i$-th element is the number of points of $S$ with $f$-value $i - 1$, for a valuation of the given row type. The columns of Table [2.2] contain the number of lines of the valuation geometry $V$ of a given type incident with an arbitrary point of the type of the column. For example, the second entry in the first column tells us that through each valuation of type $A$, there is exactly 1 line of $V$ that has type $ABB$.

| Type | $\#$ | $M_f$ | $|O_f|$ | $|H_f|$ | Value Distribution |
|------|------|------|------|------|-------------------|
| $A$  | 9    | 2    | 1    | 5    | [1, 4, 4]         |
| $B$  | 6    | 1    | 3    | 3    | [3, 6, 0]         |

Table 2.1.: The valuations of GQ(2,1)

</tbody>
</table>

Table 2.2.: The lines of the valuation geometry of GQ(2,1)

Now for any near polygon $S'$ which contains $S$ as a full subgeometry and has three points on each line, we can associate points and lines of $S'$ to the points and lines of $V$ by using Theorems [2.2.3], [2.2.6] and [2.3.2] unless all three valuations induced by points on a line of $S'$ are equal. We assign a type to the points of $S'$ based on the type of the points of $V$ they induce. The type of a line of $S'$ is simply a sorted string of the types of the points contained in the line. Thus, every point of $S'$ has type $A$ or $B$, and every line of $S'$ has type $AAA$, $ABB$ or $BBB$.

**Lemma 2.3.3.** Let $S'$ be a generalized quadrangle which contains $S$ as a full subgeometry. Then

1. every point of $S'$ is at distance at most 1 from $S$;
2. every point of $S'$ which is contained in $S$ has type $A$;
3. every point of $S'$ which is not contained in $S$ has type $B$ and is collinear with precisely three points of $S$ forming a 1-ovoid.
Proof. (1) Let \( x \) be a point of \( S' \). If \( d(x, S) \geq 2 \), then by Lemma 2.2.4, \( M_{f_x} \leq 0 \), which is a contradiction.\(^6\)

(2) Since \( S \) is a full subgeometry, by Lemma 1.2.5 it is isometrically embedded. Thus, for every point \( x \) of \( S \) the valuation \( f_x \) is classical.

(3) Let \( x \) be a point of \( S' \) which is not contained in \( S \), and hence it is at distance 1 from \( S \). Then by Lemma 2.2.4, \( M_{f_x} \leq 1 \), and hence \( x \) must be of type \( B \) by Table 2.1. Moreover, the points of \( S \) collinear with \( x \) are in bijection with the set \( O_{f_x} \), and therefore \( x \) is collinear with exactly three points of \( S \), which form a 1-ovoid.

\[\square\]

**Corollary 2.3.4.** Let \( S' \) be a generalized quadrangle containing \( S \) as a full subgeometry. Then for every line \( L = \{x_1, x_2, x_3\} \) of \( S' \), the valuations \( f_{x_1}, f_{x_2} \) and \( f_{x_3} \) of \( S \) are all mutually distinct.

**Proof.** If \( L \) is contained in \( S \), then these are three distinct classical valuations; so assume that \( L \) is not contained in \( S \). Then by Lemma 2.3.3, \( L \) either intersects \( S \) in a unique type \( A \) point, or it lies at distance 1 from \( S \) and has only type \( B \) points. In the former case, one of the three valuations is of type \( A \) while the rest are of type \( B \), and hence all of them are distinct (note that \( f_{x_1} = f_{x_2} \ast f_{x_3} \)). In the latter case, we see from Theorem 2.3.2(b) that the valuations are distinct.\[\square\]

By Corollary 2.3.4, every line \( \{x_1, x_2, x_3\} \) of \( S' \) gives rise to a line \( \{f_{x_1}, f_{x_2}, f_{x_3}\} \) of the valuation geometry \( V \).

**Lemma 2.3.5.** Let \( S' \) be a generalized quadrangle of order \( (2, 2) \) containing \( S \) as a full subgeometry. Then the map \( x \mapsto f_x \) between the points of \( S' \) and the points of \( V \) is a bijection.

**Proof.** By Proposition 1.2.4, \( S' \) has 15 points, 6 of which belong to \( S \). Since \( S \) is isometrically embedded by Lemma 1.2.5, each of the 6 points of \( S \) is in bijective correspondence with the 6 type \( A \) points of \( V \). The 9 points of \( S' \) which are not in \( S \) are at distance 1 from \( S \) and each of them is collinear with exactly three points of \( S \) forming a 1-ovoid by Lemma 2.3.3. Since there are exactly 9 points of type \( B \) in \( V \) (see Table 2.1), it suffices to show that two distinct points of \( S' \) which are not contained in \( S \) induce distinct valuations. Let \( x, y \) be two such distinct points. Suppose \( f_x = f_y \) and let \( z \) be a point of \( O_f \), which is then collinear to both \( x \) and \( y \). Then \( z \) is incident with two lines in \( S \) and since the order of \( S \) is \( (2, 2) \), it is incident with at most one other line. Thus, \( \{x, y, z\} \) is a line of \( S' \). Now let \( z' \) be any other point of \( O_f \). Then \( z' \) is collinear with both \( x \) and \( y \), which contradicts NP2.\[\square\]

**Lemma 2.3.6.** Let \( S' \) be a generalized quadrangle of order \( (2, 2) \) containing \( S \) as a full subgeometry. Then the map \( \{x_1, x_2, x_3\} \mapsto \{f_{x_1}, f_{x_2}, f_{x_3}\} \) is a bijective map between the lines of \( S' \) and the lines of \( V \) that have type \( AAA \) or \( ABB \).

**Proof.** By Corollary 2.3.4 and Lemma 2.3.5, two distinct lines of \( S' \) induce distinct lines of \( V \). By a double count using Table 2.2, there are 6 lines of type \( AAA \) and 9 lines of type \( ABB \) in \( V \). The lines contained in \( S \) are of type \( AAA \), and since there are 6 of them, they correspond bijectively to the type \( AAA \) lines of \( V \). Let \( x \) be a point of type \( B \) in \( S' \). Then

\(^{6}\)Of course a more elementary reasoning based on the GQ axiom also proves this, but we prove it this way since a similar argument will appear in other cases later.
$x$ is collinear with three points of $S$ by Lemma 2.3.3, giving rise to three lines through $x$, all necessarily of type $AAB$ as they contain a point of type $A$. Since the order of $S$ is $(2,2)$, there are no other lines through $x$. Therefore, there are no lines of type $ABB$ in $S'$. Since there are 9 lines in $S'$ besides those contained in $S$, these must bijectively correspond to the type $ABB$ lines of $V$.

**Corollary 2.3.7.** Up to isomorphism, there is at most one generalized quadrangle of order $(2,2)$ containing $S$ as a full subgeometry.

**Proof.** Every such GQ, if it exists, must be isomorphic to the subgeometry of $V$ formed by taking all the lines of type $AAA$ and $ABB$.

We can in fact show that every GQ of order $(2,2)$ contains $S$ as a full subgeometry. Take two disjoint lines $L_1 = \{x_{11}, x_{12}, x_{13}\}, L_2 = \{x_{21}, x_{22}, x_{23}\}$ in such a GQ and assume that for each $i \in \{1, 2, 3\}$ the point $x_{1i}$ is collinear with the point of $x_{2i}$. For each $i$, let $x_{3i}$ denote the third point on the line joining $x_{1i}$ and $x_{2i}$. Then from GQ2 it follows that $x_{31}, x_{32}$ and $x_{33}$ are pairwise collinear and mutually distinct. Therefore, $L_3 = \{x_{31}, x_{32}, x_{33}\}$ is a line, and we get a $(3 \times 3)$-grid formed by these lines. Corollary 2.3.7 now shows that up-to isomorphism, there is at most one GQ of order $(2,2)$. Since we already know that there exists a generalized quadrangle of order $(2,2)$, the $W(2)$ quadrangle (see Figures 1.1 and 1.2), it must be unique.

## 2.4. Some valuation geometries

In this section we record the data for valuation geometries of the split Cayley hexagon $H(2)$, its dual $H(2)^D$, and the Hall-Janko near octagon $HJ$, that will be used later. This data was obtained using the computer algorithms described in Chapter 3.

| Type | $\#M_f$ | $|O_f|$ | $|H_f|$ | Value Distribution |
|------|----------|--------|--------|-------------------|
| $A$  | 63       | 3      | 1      | $31$              | $[1, 6, 24, 32]$ |
| $B$  | 252      | 3      | 1      | 47               | $[1, 14, 32, 16]$ |

3. Computing Hyperplanes, Ovoids and Valuations

3.1. Introduction

In this chapter we describe the computational techniques we have used in our work to compute hyperplanes, ovoids and valuations of near polygons. We will construct all the Tables given in Section 2.4 by using computer models of these near polygons. We will also give a computer-aided proof of nonexistence of distance-2 ovoids (which are equivalent to 1-ovoids) in the dual split Cayley hexagon $H(4)^D$. Furthermore, these techniques will be applied in Chapter 4 to obtain some results on intersections of hyperplanes in split Cayley hexagons and their duals which will help us prove non-existence of certain generalized hexagons (see Theorem 4.3.11).

The study of distance-$j$ ovoids in generalized polygons was initiated by Thas, who investigated the existence of distance-2 ovoids in generalized quadrangles and distance-3 ovoids in generalized hexagons $[135]$ (these were simply called ovoids). In their general form, distance-$j$ ovoids were introduced by Offer and Van Maldeghem in $[113]$. These are important objects in finite geometry, with connections to perfect codes in distance-regular graphs $[44]$, cores of graphs $[43]$ and several other topics. Our focus is on distance-2 ovoids in the dual split Cayley hexagons $H(q)^D$, where $q$ is a prime power. While for the split Cayley hexagon $H(q)$, existence of these ovoids is known for $q \in \{2, 3, 4\}$ $[68]$, and the ovoids are completely classified $[69, 117]$; for $H(q)^D$, only the nonexistence for $q = 2$ and the existence for $q = 3$ (noting that $H(3) \cong H(3)^D$) is known. Therefore, our result on nonexistence of distance-2 ovoids in $H(4)^D$ is the natural next step.

In $[113]$, it was shown that a distance-3 ovoid in a generalized octagon of order $(s, t)$ can only exist if $s = 2t$. This directly implies that there are no distance-3 ovoids in the Ree-Tits octagons $GO(q, q^2)$, or their duals $GO(q^2, q)$, where $q$ is an odd power of 2, except for the case of $GO(4, 2)$. We will show that this last remaining case does not have any distance-3 ovoids either.

To be able to understand the computer code given in this, the reader needs to be familiar with the computer algebra system GAP $[82]$ and the mathematical software SageMath $[74]$. But we have tried to explain the basic ideas without referring to any specific software, so that one can implement all the algorithms in whichever language or software one is comfortable with.

$^1$After we solved this last “open case”, we found out that Brouwer had already verified it using a different computation $[33]$. Brouwer’s result is mentioned as a remark in a liber amicorum in Dutch, which leaves out some details of the used techniques. So, we still see some value in including this result in the thesis.
### 3.2. Definitions and Basic Techniques

We first recall the definition of hyperplanes and 1-ovoids, since they are going to be central to this chapter.

**Definition.** A *hyperplane* of a point-line geometry is a proper subset of the set of points with the property that every line is either contained in it or intersects it in a unique point. If a hyperplane does not contain any line, then it is called a *1-ovoid*.

**Definition.** Let $\mathcal{S} = (\mathcal{P}, \mathcal{L}, I)$ be a near polygon and let $d(\cdot, \cdot)$ denote the distance function of its collinearity graph.

(a) A *partial distance-$j$ ovoid* of $\mathcal{S}$ is a set $\mathcal{O}$ of points such that for every two distinct points $x$ and $y$ in $\mathcal{O}$ we have $d(x, y) \geq j$.

(b) A *distance-$j$ ovoid* of $\mathcal{S}$ is a partial distance-$j$ ovoid $\mathcal{O}$ such that (1) for every point $a$ of $\mathcal{S}$ there exists a point $x$ of $\mathcal{O}$ such that $d(a, x) \leq j/2$; (2) for every line $L$ of $\mathcal{S}$ there exists a point $x \in \mathcal{O}$ such that $d(L, x) \leq (j - 1)/2$.

**Remark.** The definition of distance-$j$ ovoids given in [113] looks different as it employs the distance function in the incidence graph, which is a common convention in the literature on generalized polygons. But, it can easily be shown using Proposition 1.1.1 that these two definitions are equivalent.

The *exact cover* problem in a hypergraph $(V, E)$ asks for the existence of a subset $S$ of $E$ such that for every vertex $v$ there exists a unique edge $e$ in $S$ which contains $v$. The dual of this problem is the *exact hitting set* problem where we need to find a subset $O$ of $V$ such that for every edge $e$ there is a unique vertex $v$ in $O$ which is contained in $E$. As noted before, 1-ovoids in point-line geometries, where the lines can be treated as subsets of points, are equivalent to exact hitting sets in the corresponding hypergraph. It is clear from the definitions that in a near polygon distance-2 ovoids are equivalent to 1-ovoids. We will now show that in general, distance-$j$ ovoids can be linked to exact hitting sets in certain hypergraphs.

**Lemma 3.2.1.** Let $\mathcal{S} = (\mathcal{P}, \mathcal{L}, I)$ be a near $2n$-gon. For any $i \in \{0, \ldots, n\}$ and an element $a \in \mathcal{P} \cup \mathcal{L}$, let $\Gamma_{\leq i}(a)$ denote the set of points at distance at most $i$ from $a$ in the collinearity graph of $\mathcal{S}$. Let $\mathcal{O}$ be a set of points and $j \in \{2, \ldots, n\}$. Then

1. for $j$ even, $\mathcal{O}$ is a distance-$j$ ovoid if and only if for all $L \in \mathcal{L}$ we have $|\Gamma_{\leq (j-2)/2}(L) \cap \mathcal{O}| = 1$;

2. for $j$ odd, $\mathcal{O}$ is a distance-$j$ ovoid if and only if for all $x \in \mathcal{P}$ we have $|\Gamma_{\leq (j-1)/2}(x) \cap \mathcal{O}| = 1$.

**Proof.** We only prove the first case, when $j$ is even, and note that the second part has a similar proof. Say $\mathcal{O}$ is a distance-$j$ ovoid and let $L \in \mathcal{L}$. Then by the definition of distance-$j$ ovoids there exists a point $x$ in $\mathcal{O}$ such that $d(x, L) \leq (j - 1)/2$, but since $j$ is even and distances are integral we have $d(x, L) \leq (j - 2)/2$. Say there was another

---

\footnote{One side of this Lemma was proved in [57, Lemma 2].}
point \( y \neq x \) in \( O \) with \( d(y, L) \leq (j - 2)/2 \). Then \( d(x, y) \leq d(x, L) + d(y, L) + 1 = j - 1 \) which is a contradiction. Now say \( O \) is a set of points such that for every line \( M \) we have \(|\Gamma_{\leq(j/2)}(M) \cap O| = 1\). Let \( x, y \) be two distinct points in \( O \). If \( d(x, y) \leq j - 1 \), then there exists a line \( L \) in the path joining \( x \) to \( y \) such \( d(x, L) \leq (j - 2)/2 \) and \( d(y, L) \leq (j - 2)/2 \), which is not possible. Now let \( x \) be an arbitrary point of \( S \). Let \( L \) be any line through \( x \), and let \( y \) be the unique point in \( O \) such that \( d(L, y) \leq (j - 2)/2 \). Then \( d(x, y) \leq 1 + d(L, y) = j/2 \). Let \( L \) be an arbitrary line of \( S \); then by the assumption on \( O \) there exists a point in \( O \) at distance at most \((j - 2)/2 \leq (j - 1)/2\) from \( L \). Therefore, \( O \) is a distance-\( j \) ovoid. \hfill \Box

Lemma 3.2.1 makes it clear that the existence of a distance-\( j \) ovoid in a near \( 2n \)-gon \( S \) is equivalent to the existence of an exact hitting set in a hypergraph derived from the collinearity graph of \( S \). For \( j \) even the edges of this hypergraph are the subsets \( \Gamma_{\leq(j/2)}(L) \) of \( P \) where \( L \) is a line, and for \( j \) odd the edges of this hypergraph are the subsets \( \Gamma_{\leq(j/2)}(x) \) where \( x \) is a point.

Note that the exact cover problem is a well-known NP-hard problem, and hence we cannot expect a “really efficient” algorithm for computing distance-\( j \) ovoids in general. Still, we can do better than brute force search. One of the fastest known algorithms for computing exact covers is Knuth’s Dancing Links \[98\]. It can be implemented from scratch in any programming language, or one can use some existing implementation. We will be using the standard implementation in SageMath \[74\], which is due to Carlo Hamalainen\[3\]. The following function written in SageMath will give us an iterator for all exact hitting sets in a hypergraph, or equivalently all 1-ovoids in the corresponding point-line geometry.

```python
def ovoids(P, L):
    """
    Find all exact hitting sets (1-ovoids) in a hypergraph (geometry).
    """
    map = dict() # to construct the dual problem of exact covers
    for p in P:
        map[p] = []
    for i in range(len(L)):
        for p in L[i]:
            map[p].append(i)
    E = [map[p] for p in P]
    for match in DLXCPP(E):
        yield [P[i] for i in match]

To see how one can use this function, we determine all 1-ovoids of a \((3 \times 3)\)-grid (this corresponds to the type \( B \) valuation given in Table 2.1).

[https://carlo-hamalainen.net/blog/2008/3/1/an-exact-cover-solver-for-sage]
P = [1,2,3,4,5,6,7,8,9]
L = [[1,2,3],[4,5,6],[7,8,9],[1,4,7],[2,5,8],[3,6,9]]
O = ovoids(P, L)
print list(O)
    [[1, 5, 9], [1, 6, 8], [2, 4, 9], [2, 6, 7], [3, 4, 8], [3, 5, 7]]

Finally we mention that distance-$j$ ovoids in near polygons also give rise to valuations as follows. Let $O$ be a distance-$j$ ovoid of a near polygon $S = (P, L, I)$ for $j$ even. Then the function $f: P \to \mathbb{N}$ defined by $f(x) = d(x, O)$ is a valuation of $S$, with $M_f = j/2$. We will not encounter distance-$j$ ovoidal valuations in this thesis, and we refer the interested reader to [64] for more details.

### 3.3. Computer Models of Geometries

Since we want to compute the valuation geometries of some “small” near polygons, and compute certain substructures like distance-$j$ ovoids and hyperplanes in these near polygons, we will need computer models that we can work with. In this section we discuss how we can obtain the computer models of some small split Cayley hexagons, their duals, the Ree-Tits octagon $GO(2,4)$, and the Hall-Janko near octagon $HJ$.

To construct a computer model of the split Cayley hexagons (and their duals), one can use the definition mentioned in Section 1.2.1 which involves a particular quadric in $PG(6, q)$. This is what the GAP [82] package FinIng [15] does. However, for the small cases that we consider in this thesis, we prefer a different construction. Observing that the automorphism groups of these geometries act *primitively* and *distance transitively* (see for example [40]) on both points and lines of the geometry, we can use the permutation representations given in the database of primitive permutation groups of GAP (works only for $q \in \{2, 3, 4\}$) or the permutation representations given in the ATLAS of finite simple group [54] (works for $q \in \{2, 3, 4, 5\}$) to construct the points and lines of these geometries. This method also works for other geometries, like the generalized hexagons of order $(q, 1)$ obtained from $PG(2, q)$ (for small $q$), the generalized octagons of order $(q, 1)$ (for small even $q$), the Ree-Tits octagons and for the Hall-Janko near octagon.

Since for characteristic not equal to 3 we have two non-isomorphic permutation representations of the automorphism group of the split Cayley hexagons, one on the points of split Cayley hexagon and another one on the points of its dual (which is non-isomorphic in this case), we need a way to distinguish between these two. An easy combinatorial method of doing so was given by Ronan in [120], which we have used to find out which permutation representation corresponds to the dual split Cayley. The following function, written in GAP, constructs a near polygon with permutation group $G$ acting distance transitively on its points, and transitively on the lines. As input, the function only requires the permutation group $G$ acting on the set $\{1, \ldots, v\}$ for some integer $v$ and an array `partition_sizes` whose $i$-th entry denotes the number of points at distance $i - 1$ from a fixed point in the geometry\(^4\). We assume that all these entries are distinct, a condition which is satisfied by all our examples. Since we have a near polygon, we can

---

\(^5\)the index of an array in GAP start from 1
construct a line (and hence all lines via transitivity of the group) by taking the intersection \( x^\perp \cap y^\perp \) of two collinear points \( x \) and \( y \) (\( p^\perp \) is equal to the set of points at distance at most 1 from \( p \) for any point \( p \)).

\[
\text{construct\_geometry} := \text{function}(G, \text{partition\_sizes}) \\
\text{local } v, i, j, k, \text{temp}, \text{points}, \text{orbs}, \text{perp1}, \text{perp2}, \text{lines}, \text{partition}, D, d; \\
v := \text{Sum}(\text{partition\_sizes}); \\
\text{points} := [1..v]; \\
\text{orbs} := \text{Orbits}(%\text{Stabilizer}(G,1),\text{points});; \\
\text{partition} := []; \\
\text{for } i \text{ in } \text{partition\_sizes} \text{ do} \\
\quad \text{Add}(\text{partition}, \text{Filtered(\text{orbs}, } x \rightarrow \text{Size}(x) = i)[1]); \\
\quad \# \text{ this is where we use the assumption that the entries are distinct} \\
\text{od}; \\
\text{perp1} := \text{Union}([1],\text{partition}[2]); \\
\text{perp2} := \text{OnSets}(%\text{perp1},\text{RepresentativeAction}(G,1,\text{partition}[2][1])); \\
\text{lines} := \text{Orbit}(G, \text{Intersection}(\text{perp1}, \text{perp2}), \text{OnSets}); \\
D := \text{NullMat}(v, v); \\
\text{for } i \text{ in } [1..v] \text{ do} \\
\quad \text{for } j \text{ in } [i+1..v] \text{ do} \\
\quad \quad k := j^\text{RepresentativeAction}(G,i,1); \\
\quad \quad \text{temp} := 0; \\
\quad \quad \text{while not (}k \text{ in } \text{partition[temp+1]}\text{) do temp := temp + 1; od; } \\
\quad \quad D[i][j] := \text{temp}; D[j][i] := \text{temp}; \\
\quad \quad \text{od}; \\
\text{od}; \\
d := \text{function}(x,y) \\
\quad \text{return } D[x][y]; \\
\text{end}; \\
\text{return } [\text{points}, \text{lines}, d]; \\
\text{end};
\]

Using this function, we can construct the computer models of all the geometries we will need in this thesis. We include the GAP code that can be used along with the function defined above to make these models. Recall that the number of points in \( H(q) \) is \((1+q)(1+q^2+q^4)\) and its automorphism group has size \( rq^6(q^6-1)(q^2-1) \) where \( q = p^r \) for some prime \( p \). The automorphism group of the Hall-Janko near octagon \( HJ \) is \( J_2:2 \) and has size 1209600, which acts primitively and distance-transitively on its 315 points with suborbit sizes (the entries of \text{partition\_sizes}) 1, 10, 80, 160 and 64. The automorphism group of the Ree-Tits octagon \( GO(2,4) \) has size 35942400, and it acts primitively and distance-transitively on its 1755 points with suborbit sizes 1, 10, 80, 640, 1024.

\[
\# \text{H}(2) \\
G := \text{AllPrimitiveGroups(DegreeOperation, 63, Size, 12096)}[2]; \\

# H(4)
G := AllPrimitiveGroups(DegreeOperation, 1365, Size, 503193600)[1];
H4 := construct_geometry(G, [1, 20, 320, 1024]);

# H(4)^D
G := AllPrimitiveGroups(DegreeOperation, 1365, Size, 503193600)[2];
H4D := construct_geometry(G, [1, 20, 320, 1024]);

# GO(2, 4)
G := AllPrimitiveGroups(DegreeOperation, 1755, Size, 35942400)[1];
Ree-Tits := construct_geometry(G, [1, 10, 80, 640, 1024]);

Finally we note that there is a database of small generalized polygons maintained by Moorhouse [110] that one can use to construct these computer models.

### 3.4. Valuation Geometries

While ovoidal, semi-classical and distance-\( j \) ovoidal valuations of a near polygon \( S \) can in principle be computed using the Dancing Links algorithm in a reasonably fast way, we do not have any efficient way of doing so for other valuations (except of course the classical valuations). The case when every line of \( S \) has three points is different. Then we have the following characterization of hyperplanes, which can be turned into an algorithm for computing valuations and valuation geometries of these near polygons.

**Proposition 3.4.1.** Let \( S = (P, L, I) \) be a (finite) partial linear space with three points on each line and let \( v = |P| \). For any subset \( S \) of \( P \), let \( \chi(S) \) denote the binary vector in the vector space \( \mathbb{F}_2^v \) whose \( i \)-th entry is 1 if the \( i \)-th point (after fixing an ordering of \( P \)) of \( S \) lies in \( S \) and 0 otherwise. Then a proper subset \( H \) of \( P \) is a hyperplane of \( S \) if and only if \( \chi(P \setminus H) \neq 0 \) is orthogonal to \( \chi(L) \) for every \( L \in L \) with respect to the standard inner product on \( \mathbb{F}_2^v \).

**Proof.** Let \( L \) be a line of \( S \). Since \( |L| = 3 \), the statement “\( L \) is either contained in \( H \) or intersects \( H \) in exactly one point” is equivalent to \( |L \cap H| \in \{1, 3\} \). Therefore, \( H \) is a hyperplane if and only if for all lines \( L \), we have \( |L \cap (P \setminus H)| \in \{0, 2\} \) which is equivalent to \( \chi(L) \cdot \chi(P \setminus H) = 0 \) in \( \mathbb{F}_2^v \). \( \square \)
Corollary 3.4.2. Let $\mathcal{H}$ be the set of hyperplanes of a (finite) near polygon $S = (P, L, I)$ that has three points on each line. Then the set \( \{ \chi(P \setminus H) \mid H \in \mathcal{H} \} \cup \{0\} \) is equal to the null space of the $|L| \times |P|$ incidence matrix of $S$ over $\mathbb{F}_2$.

By Corollary 3.4.2, computing the set of hyperplanes of near polygons with three points on each line is equivalent to a computation of the null space of a binary matrix. Instead of storing all the elements of this null space, we would like to store only the non-isomorphic ones under the action of the automorphism group of the near polygon. To do so we use Linton’s smallest image set algorithm [105], which has been implemented in the GRAPE package [130] of GAP. The function `SmallestImageSet(H, S)` returns the lexicographically smallest element of the orbit of the set $S$ under the action of the group $H$. For the rest of this section assume that we are only talking about near polygons with three points on each line.

In the following GAP code, we compute the distinct representatives of the isomorphism classes of hyperplane complements of a near polygon $S$ that has three points on each line. It requires the automorphism group, points, lines, diameter and the distance function of $S$, stored in the variables $G$, `points`, `lines`, `diam` and `dist`, respectively. We also assume that $G$ acts transitively on the points so that all singular hyperplanes are isomorphic. To speed up the process we start with the singular hyperplanes, for which we have a variable `singular_compl` that contains the set of points opposite to a fixed point.

```gap
SetVect := function(S)
    #I: subset of points
    #O: characteristic vector of S
    return One(GF(2))*List(points, function(i) if i in S then return 1; else return 0; fi; end);
end;

VectSet := function(v)
    #I: characteristic vector
    #O: subset of points corresponding to v
    return Set(Filtered(points, i->v[i]=One(GF(2))));
end;

IncidenceMatrix := TransposedMat(List(lines, SetVect));;
Y := NullspaceMat(IncidenceMatrix);
U := Subspace(GF(2)^Size(points)),Y);

LoadPackage("grape");
hypcomplements := NewDictionary(Set([1,2,3]), false);
singular_compl := Filtered(points, x -> dist(x, 1) = diam);
AddDictionary(hypcomplements, SmallestImageSet(G,Set(singular_compl)));
balance := 2^Dimension(U)- 1 - Size(points);

while balance > 0 do
    w := Random(U);
```

---

6I learned this trick from Bart De Bruyn, who in turn learned it from Sergey Shpectorov.
if \( w \neq \text{Zero}(U) \) then
    \( \text{compl} := \text{VectSet}(w) \);
    \( S := \text{SmallestImageSet}(G, \text{compl}) \);
    if not \( \text{KnowsDictionary}(\text{hypcomplements}, S) \) then
        \( \text{AddDictionary}(\text{hypcomplements}, S) \);
        \( \text{balance} := \text{balance} - \text{Index}(G, \text{Stabilizer}(G, S, \text{OnSets})) \);
    fi;
fi;
od;

\( \text{hypcomplements} := \text{hypcomplements}!.\text{list} \);

At the end of this computation we will have a list of all hyperplane complements, and hence hyperplanes of the near polygon \( \mathcal{S} \). As an example, let \( \mathcal{S} \) be isomorphic to \( \text{H}(2) \). Then computation done by the code above quickly shows that \( \mathcal{S} \) has 25 distinct hyperplanes up to isomorphism. This number coincides with that obtained by Frohardt and Johnson \[81\] who classified all hyperplanes of \( \text{H}(2) \) and \( \text{H}(2)^D \).

From these hyperplanes, we would now like to construct the valuation geometry of \( \mathcal{S} \). Firstly, while every valuation \( f \) of \( \mathcal{S} \) gives rise to a hyperplane \( H_f \), not every hyperplane is going to give rise to a valuation of \( \mathcal{S} \). An example of this situation is given in Figure 1.2 where the subgrid is a hyperplane which is not of valuation type (try to see this using the Algorithm described below). So, we will pick a hyperplane complement and use it to try to construct a semi-valuation in which every point in the hyperplane complement has a constant value and every point not in the hyperplane complement has value strictly less than that constant. Note that once we have assigned values to two points of a line of \( \mathcal{S} \), then the value of the third point is automatically determined. Using these ideas, we have Algorithm 1. We note that this idea of constructing valuations is due to De Bruyn \[62\].

We define a partial valuation of \( \mathcal{S} \) as a function \( f \) defined on a subspace \( S_f \) of \( \mathcal{S} \) such that \( f \) is a semi-valuation on the subgeometry of \( \mathcal{S} \) induced on \( S_f \). In Algorithm 1, we use a function \( \text{AssignValue} \) which takes as input a function \( f \) defined on a set \( S \) of points, a point \( x \) and a value \( i \), and finds a partial valuation \( g \) such that: (i) \( S_g \) is the smallest subspace containing \( S \) and \( \{x\} \); (ii) \( g(y) = f(y) \) for all \( y \in S \); (iii) \( g(x) = i \). If such a function \( g \) does not exist then \( \text{AssignValue} \) returns \( \text{fail} \). An implementation of this function and Algorithm 1 in GAP will follow. Note that we start with assigning value 0 to all points of a given hyperplane complement, and thus every other point will get a value from the set \( \{-1, -2, \ldots, -n\} \) where \( n \) is the diameter of \( \mathcal{S} \).

We now give the GAP code based on Algorithm 1 which we have used to compute all valuations.

```
MakeClosure := function(val)
    local X,x,L,f,S,V;
    f := ShallowCopy(val);
    X := Filtered(points, x -> val[x] <> fail);
    for L in lines do
        S := Intersection(L,X);
        if Size(S) = 2 then
            \text{// Code for constructing a semi-valuation}
        fi;
    od;
end;
```
Algorithm 1 Create valuations

*input:* a hyperplane complement $H$

*output:* list of all semi-valuations $f$ for which $\overline{H_f} = H$ and for which the maximal value is equal to 0

$$
complete \leftarrow []$$

$$
incomplete \leftarrow []$$

$$

if ForAll(points, x -> temp[2][x] <> fail) then Add(complete, temp[2]);
else Add(incomplete, temp[2]);
fi;
while incomplete <> [] do
    val := Remove(incomplete);
    p := Filtered(points, x -> val[x] = fail)[1];
    for i in [1..diam] do
        temp := AssignValue(val, p, -i);
        if temp[1] then
            if ForAll(points, x -> temp[2][x] <> fail) then
                if not ForAny(complete, f -> AreIsomorphicVal(f, temp[2])) then
                    Add(complete, temp[2]);
                    fi;
                else Add(incomplete, temp[2]);
                fi;
            fi;
        od;
    od;
return Set(complete, L -> List(L, x -> x - Minimum(L)));
end;

Valuations := [];
for h in hypcomplements do
    S := CreateVal(h);
    if S <> [] then
        Append(Valuations, S);
        fi;
    od;

Once we have all the valuations of \( S \), we can easily construct the first table in the description of the valuation geometry \( V \) of \( S \). For the second table, and to verify other properties of \( V \), we still need the lines of \( V \). To construct the lines, we simply go through pairs \( \{f_1, f_2\} \) of all valuations, check if they are neighboring, and if they are then compute \( f_1 \ast f_2 \) to construct the line \( \{f_1, f_2, f_1 \ast f_2\} \) of \( V \). We do so in the following GAP code. We assume that there is a user defined function TypeVal which takes as input a valuation and returns its type, which can be any string that identifies the different non-isomorphic valuations. For example, we use the following function for \( H(2)^D \) (see Table 2.3).

TypeVal := function(val)
local h, M, x;
M := Maximum(val);
h := Filtered(points, x -> val[x] = M);
if Size(h) = 32 and M = 3 then return 'A'; fi;
if Size(h) = 40 then return 'C'; fi;
if Size(h) = 16 then return 'B'; fi;
return 'D';
end;

As noted in Section 2.4 these point types are used to give types to the lines of \( V \). In the following code, we give some functions that can be used to find the types of all lines.
through a fixed point of $V$, which is what we need to construct the second table that describes the valuation geometry $V$.

\begin{verbatim}
Isneighboring := function(val1, val2)
#I: two valuations val1 and val2
#O: returns whether they are distinct and neighboring
   local S;
   if val1 = val2 then return false; fi;
   S := List(points, x -> val1[x] - val2[x]);
   Sort(S);
   if S[Size(S)] - S[1] > 2 then return false; fi;
   return true;
end;

Epsilon := function(val1, val2)
#I: two distinct neighboring valuations val1 and val2
#O: the integer $e$ for which $|val1(x) - val2(x) + e| \leq 1$
   local e, p, L, x1, x2;
   for L in lines do
      x1 := Filtered(L, x -> val1[x] = Minimum(val1{L}))[1];
      x2 := Filtered(L, x -> val2[x] = Minimum(val2{L}))[1];
      if x1 <> x2 then break; fi;
   od;
   return val2[x2] - val1[x1];
end;

ThirdFromTwo := function(val1, val2)
#I: two valuations val1 and val2
#O: the new valuation val1*val2
   local e, x, val3;
   e := Epsilon(val1, val2);
   val1 := val1 + e;
   val3 := 0*points;
   for x in points do
      if val1[x] = val2[x] then val3[x] := val1[x] - 1;
      else val3[x] := Maximum([val1[x], val2[x]]);
      fi;
   od;
   return val3 - Minimum(val3);
end;

ThroughPoint := function(s, S)
#I: a member s of the list Valuations and a list S of some valuations
#O: the types of lines through point s of the valuation geometry
   # when the other two points (valuations) lie in set S
   local val1, val2, val3, L, types, x, g, i, T;
   val1 := s;
   types := Set([]);
\end{verbatim}
for val2 in S do
    if Isneighboring(val1, val2) then
        val3 := ThirdFromTwo(val1, val2);
        if val3 in S then
            L := [val1, val2, val3];
            T := [TypeVal(val1), TypeVal(val2), TypeVal(val3)]; Sort(T);
            i := Position(List(types, x -> x[1]), T);
            if i <> fail then types[i][2] := types[i][2] + 1/2;
            else AddSet(types, [T,1/2]); fi;
        fi;
    fi;
od;
return types;
end;

GenerateOrbit := function(s)
#I: a valuation s
#O: the orbit of this valuation under the action of group G
    return Set(G, g -> List(points, x -> s[x^Inverse(g)]));
end;

Table2 := [];
S := Set([]);
for s in Valuations do S := Union(S,GenerateOrbit(s)); od;
for s in Valuations do
    Add(Table2,[TypeVal(s), ThroughPoint(s,S)]);
od;

After this computation, the variable Table2 contains a list whose $i$-th entry corresponds to a type of the valuation and the number of lines of each type through a valuation of that type. For example, when $S$ is isomorphic to $H(2)^D$ we have the following entries (see Table 2.4):

['C',[['"ACC"",1],["BCC",2],["CCC",8],["CCD",40],["CDD",4]]
['D',[['"ADD"",3],["BDD",2],["CCD",5],["CDD",6],["DDD",10]]
['A',[['"AAA"",3],["ABB",2],["ACC",2],["ADD",24]]]
['B',[['"ABB"",1],["BBB",4],["BCC",1],["BDD",4]]

3.5. Distance-2 ovoids in $H(4)^D$

While it can be directly shown using the Dancing Links algorithm that $H(2)^D$ does not have any distance-2 ovoids, for $H(4)^D$ this does not work. We can use the automorphism group of $H(4)^D$ to perform some sort of symmetry breaking (see for example [117]), but even then it does not seem likely that we will get any results in a reasonable time frame. The main idea that makes this computational problem feasible is as follows:
First classify all distance-2 ovoids in a fixed subhexagon isomorphic to H(4, 1) up to isomorphism under the action of the stabilizer of H(4, 1), and then see if any of these ovoids can be extended to a distance-2 ovoid of H(4)^D.

We have implicitly assumed that every distance-2 ovoid of H(4)^D will induce a distance-2 ovoid of its subhexagon isomorphic to H(4, 1). This is justified by the following lemma.

**Lemma 3.5.1.** Let \( S \) be a generalized hexagon of order \((s, t)\). Let \( \mathcal{H} \) be a subhexagon of \( S \) that has order \((s, t')\) and let \( \mathcal{O} \) be a distance-2 ovoid of \( S \). Then \( \mathcal{O} \cap \mathcal{H} \) is a distance-2 ovoid of \( \mathcal{H} \) and

\[
|\mathcal{O} \cap \mathcal{H}| = s^2 t'^2 + st' + 1.
\]

**Proof.** By Lemma 3.2.1, \( \mathcal{O} \) is a distance-2 ovoid if and only if it meets every line in a unique point. If each line of \( S \) meets \( \mathcal{O} \) in exactly 1 points, then the same is true for \( \mathcal{H} \). Moreover, the number of lines in a generalized hexagon of order \((s, t)\) is \((1+t)(1+st+s^2 t^2)\), and thus by double counting, the number of points in a distance-2 ovoid is \((1 + st + s^2 t^2)\). Therefore, we have \( |\mathcal{O} \cap \mathcal{H}| = s^2 t'^2 + st' + 1 \). \( \square \)

We note that the stabilizer of a subgeometry of H(4)^D which is isomorphic to H(4, 1), under the action of the automorphism group of Aut(H(4)^D) is in fact isomorphic to Aut(H(4, 1)). From the definition of H(q, 1) as the dual of the incidence graph of PG(2, q), it directly follows that a distance-2 ovoid in H(q, 1) corresponds to a perfect matching of the incidence graph of PG(2, q). It is folklore that the number of perfect matchings in a balanced bipartite graph corresponds to the permanent of the biadjacency matrix of that graph. The following can be verified by computing the corresponding permanent.

**Lemma 3.5.2** ([127, A000794]). The number of perfect matchings in the incidence graph of PG(2, 4) is 18534400.

Since a perfect matching of a bipartite graph is nothing but an exact cover, we can use Knuth’s Dancing Links algorithm to enumerate all of these 18534400 distance-2 ovoids of H(4, 1), and then by using Linton’s smallest image set algorithm in exactly the same way as done in Section 3.4, we can find out the number of distinct distance-2 ovoids up to isomorphism.

**Proposition 3.5.3.** Let \( G \) be the automorphism group of H(4)^D. Let \( \mathcal{H} \) be a subhexagon of H(4)^D isomorphic to H(4, 1). Then there are exactly 350 non-isomorphic distance-2 ovoids in \( \mathcal{H} \) with respect to \( G \mathcal{H} \), the stabilizer of \( \mathcal{H} \) under the action of \( G \).

Once we have computed these 350 partial distance-2 ovoids of H(4, 1), it remains to show that none of them can be extended to a full distance-2 ovoid. For this, we use the following approach suggested by F. Ihringer which involves Integer Linear Programming (ILP). Let \( \mathcal{S} = (\mathcal{P}, \mathcal{L}, \mathcal{I}) \) be a near 2n-gon. Let \( \mathcal{O'} \) be a possibly empty set of points which forms a partial distance-j ovoid for some \( j \in \{2, \ldots, n\} \), i.e., every pair of points in \( \mathcal{O'} \) are at distance at least \( j \) in the point graph. Let \( H = (V, E) \) be the hypergraph as defined above, with \( V = \mathcal{P} \) and

\[
E = \begin{cases} 
\{ \Gamma_{\leq (j-2)/2}(L) : L \in \mathcal{L} \} & \text{if } j \text{ is even} \\
\{ \Gamma_{\leq (j-1)/2}(p) : p \in \mathcal{P} \} & \text{if } j \text{ is odd}.
\end{cases}
\]
For each \( p \in \mathcal{P} \) let \( X_p \in \{0, 1\} \) be a binary variable. Then the equations

\[
X_p = 1 \quad \text{for all } p \in \mathcal{O}'
\]

\[
\sum_{p \in e} X_p = 1 \quad \text{for all } e \in \mathcal{E}
\]

(3.1)

have an integer solution if and only if \( \mathcal{S} \) possesses a distance-\( j \) ovoid that contains \( \mathcal{O}' \). Similarly, the equations

\[
X_p = 1 \quad \text{for all } p \in \mathcal{O}'
\]

\[
\sum_{p \in e} X_p \leq 1 \quad \text{for all } e \in \mathcal{E}
\]

(3.2)

have an integer solution if and only if \( \mathcal{S} \) possesses a partial distance-\( j \) ovoid that contains \( \mathcal{O}' \).

Once we have cast the given problem as such an integer linear programming (ILP), we can use fast ILP solvers like Gurobi and CPLEX to solve the original problem. In fact, if we take \( \mathcal{O}' = \emptyset \), then this method can alternately be used to test existence of distance-\( j \) ovoids in near polygons. This is what we do for the case of GO(4, 2), where by using Gurobi we have verified that there is no distance-3 ovoid.

For each of the 350 partial distance-2 ovoids \( \mathcal{O}' \) of H(4)\(^D\) we can now define a integer linear optimization problem as in (3.1). Then the ILP solvers quickly show that these equations are infeasible for all of the 350 cases. Our full code for this computation is available online.

Remark. For the next open case, H(5)\(^D\), our algorithmic approach fails for several reasons:

1. The incidence graph of PG(2, 5) has 4598378639550 perfect matchings while the automorphism group of PG(2, 5) has size only 744000. So a classification of all non-isomorphic distance-2 ovoids of H(5, 1) seems out of reach via current methods.

2. Even for one given distance-2 ovoid of H(5, 1), the corresponding integer linear program takes too long to solve with state-of-the-art ILP solvers.

Finally we note that our techniques can also be used to give upper bounds on the size of a partial distance-2 ovoid in H(q)\(^D\), via the following lemma.

Lemma 3.5.4. Let \( \mathcal{O} \) be a partial distance-2 ovoid of H(q)\(^D\). Suppose that no subhexagon \( \mathcal{H} \) of H(q)\(^D\) isomorphic to H(q, 1) contains \( q^2 + q + 1 \) points of \( \mathcal{O} \), which necessarily form a distance-2 ovoid of \( \mathcal{H} \). Then \( |\mathcal{O}| \leq (q^2 - q + 1)(q^2 + q) \)

Proof. We double count \( (p, \mathcal{H}) \), where \( \mathcal{H} \) a subhexagon of H(q)\(^D\) isomorphic to H(q, 1) and \( p \in \mathcal{O} \cap \mathcal{H} \). From [138, Corollary 1.8.6] it follows that through every pair of opposite lines in H(q)\(^D\), there is a unique subhexagon isomorphic to H(q, 1). Via an easy counting

\( \text{http://math.ihringer.org/data.php} \)
argument, we then know that each point is contained in $(1 + q)q^3/2$ subhexagons isomorphic to $H(q, 1)$, which tells us that there are $|\mathcal{O}|(1 + q)q^3/2$ such pairs. We also know that there are $q^3(1 + q)(q^2 - q + 1)/2$ subhexagons of $H(q)^D$ which are isomorphic to $H(q, 1)$. Under the condition $|\mathcal{O} \cap \mathcal{H}| \leq q^2 + q$ this yields $|\mathcal{O}| \leq (q^2 - q + 1) \cdot (q^2 + q)$.

For $q = 2$, Lemma 3.5.4 gives us $|\mathcal{O}| \leq 18$ and for $q = 4$ it gives us $|\mathcal{O}| \leq 260$ under the given assumption that $\mathcal{O}$ does not intersect a given subhexagon in $q^2 + q + 1$ points. We can now use the following computational approach. If the ILP defined in (3.2) does not have a solution larger than some integer $b \geq (q^2 - q + 1)(q^2 + q)$ for all non-isomorphic distance-2 ovoids of $H(q, 1)$, then we obtain $b$ as an upper bound on the size of a partial distance-2 ovoid. Using this approach, so far we have been able to show that every partial distance-2 ovoid in $H(4)^D$ has size at most 265. With more time, we might be able to determine the exact bound in this case.
4. Generalized Hexagons Containing a Subhexagon

4.1. Introduction

Tits posed the following question about generalized polygons (see [138, Section 1.7.8]):

Does there exist a generalized $2n$-gon, $n \geq 2$, of order $(s, \infty)$ where $s \in \mathbb{N} \setminus \{0, 1\}$ and $\infty$ is any infinite cardinal?

Such a generalized polygon is called semi-finite. Note that by Proposition 1.2.1(1), no such generalized $(2n+1)$-gon can exist. This problem turned out to be extremely hard and the only progress that has been made so far is in the case of $n = 2$ and $s \in \{2, 3, 4\}$, where non-existence is proved by Cameron [41] for $s = 2$, Brouwer [32] and Kantor (unpublished) for $s = 3$, and Cherlin [46] for $s = 4$. A modified, and easier, version of the question that can be asked is as follows:

Given a finite generalized $2n$-gon $S$, $n \geq 2$, of order $(s, t)$, with $s \in \mathbb{N} \setminus \{0, 1\}$, does there exist a generalized $2n$-gon of order $(s, \infty)$ containing $S$ as a subgeometry?

In this chapter, we will solve this problem for $n = 3$ and $s, t \in \{2, 3, 4\}$ with $s = t$, when $S$ is one of the known generalized hexagons of order $s$, by proving non existence of a semi-finite generalized hexagon containing $S$. In fact, we will prove much more in some specific cases. We will show that for $s \in \{2, 4\}$, if $S$ is isomorphic to the split Cayley hexagon $H(s)$, then there is no generalized hexagon with $s + 1$ points on each line which contains $H(s)$ as a proper subgeometry. And in Section 4.2 we will prove our results in the more general setting of near hexagons.

4.2. Near Hexagons of Order $(2, t)$

In this section we prove the following theorem by using valuation theory and the classification result of Cohen and Tits [53] which states that every finite generalized hexagon with 3 points on each line is isomorphic to $H(2, 1)$, $H(2)$, $H(2)^D$ or $T(2, 8)$.

**Theorem 4.2.1.** Let $S'$ be a near hexagon with three points on each line containing a generalized hexagon $S$ of order 2 as an isometrically embedded subgeometry. Then the following holds:

1. $S'$ is finite;
(2) if $S$ is isomorphic to $H(2)^D$, then $S$ is a generalized hexagon and hence isomorphic to $H(2)^D$ or $T(2, 8)$;

(3) if $S$ is isomorphic to $H(2)$ and $S$ is a generalized hexagon, then $S' = S$.

**4.2.1. Near Hexagons Containing $H(2)^D$**

For this section, let $S'$ be a near hexagon which contains $S \cong H(2)^D$ isometrically embedded in it as a full and proper subgeometry. Let $\mathcal{V}$ be the valuation geometry of $S$. From Table 2.3 and the basic theory of valuations discussed in Chapter 2 we see that every point $x$ of $S'$ has type $A$, $B$, $C$ or $D$, depending on the type of the valuation $f_x$ of $S$ it induces. If $L = \{x_1, x_2, x_3\}$ is a line of $S'$, then $\{f_{x_1}, f_{x_2}, f_{x_3}\}$ is either a line of $\mathcal{V}$ and thus has one of the 11 types mentioned in Table 2.4 or $f_{x_1} = f_{x_2} = f_{x_3}$ in which case $L$ has the type $XXX$ for some $X \in \{A, B, C, D\}$. We will sometimes refer to the points and lines of $\mathcal{V}$ as $\mathcal{V}$-points and $\mathcal{V}$-lines.

**Lemma 4.2.2.** (1) Every point of $S'$ has distance at most 1 from $S$.

(2) Every point $x$ of $S$ has type $A$, and the valuation $f_x$ is classical with center $x$.

(3) Every point $x$ at distance 1 from $S$ has type $C$ and is collinear with a unique point $x'$ of $S$. Moreover, $O_{f_x} = \{x'\}$.

**Proof.** Let $x$ be a point of $S'$. If $d(x, S) \geq 2$, then by Lemma 2.2.4 $M_{f_x} \leq 1$, which is not possible since every valuation of $S$ has maximum value at least 2 by Table 2.3. Therefore, every point is at distance at most 1 from $S$. We have already seen in Theorem 2.2.3 that points of $S$ induce classical valuations of $S$, and hence they are of type $A$.

Let $x$ be a point not contained in $S$. Then since $d(x, S) = 1$, by Lemma 2.2.4 we have $M_{f_x} \leq 2$, and therefore $x$ is either of type $C$ or $D$ (type $A$ and $B$ valuations have maximum value 3). Suppose that $x$ is of type $D$. From Table 2.3 we see that there are five points of $S$ with $f_x$-value 0 giving rise to five points in $S$ collinear with $x$, and thus five lines through $x$ intersecting $S$ in a point. By Table 2.4 each of these lines must have type $ADD$. The five lines of $\mathcal{V}$ induced by these five lines of $S'$ are mutually distinct since the five classical valuations contained in them are mutually distinct (as their centers are distinct). A contradiction follows from the fact that through a given $\mathcal{V}$-point of type $D$, there are only three distinct $\mathcal{V}$-lines of type $ADD$ (see the entry in row $ADD$ and column $D$ in Table 2.4). Therefore, $x$ is of type $C$ and thus $|O_{f_x}| = 1$, which implies that $x$ is collinear with a unique point $x'$ of $S$ such that $O_{f_x} = \{x'\}$.

**Corollary 4.2.3.** Every point of $S'$ has type $A$ or $C$ and every line of $S'$ has type $AAA$, $ACC$ or $CCC$. Moreover, every point of type $C$ is incident with a unique line of type $ACC$.

**Corollary 4.2.4.** For every line $L = \{x_1, x_2, x_3\}$ of $S'$ the valuations $f_{x_1}, f_{x_2}$ and $f_{x_3}$ are mutually distinct and hence they form a line of $\mathcal{V}$.

**Proof.** The proof is similar to that of Corollary 2.3.4.

Let $\psi$ be the map between points and lines of $S'$ and points and lines of $\mathcal{V}$ defined by $\psi(x) = f_x$ and $\psi(\{x_1, x_2, x_3\}) = \{f_{x_1}, f_{x_2}, f_{x_3}\}$. Then Corollary 4.2.3 implies that $\psi$ maps a point of $S'$ to a $\mathcal{V}$-point of type $A$ or $C$ and maps a line of $S'$ to a $\mathcal{V}$-line of type $AAA$, $ACC$ or $CCC$.
ACC or CCC. Also note that every point of $S'$ which is not contained in $S$, and hence lies in $\Gamma_1(S)$ by Lemma 4.2.2, is incident with a unique line that intersects $S$ and this line has type ACC.

**Lemma 4.2.5.** Let $V'$ be the subgeometry of $V$ formed by taking the points of type $C$ and the lines of type CCC. Then $V'$ is connected.

**Proof.** This can be easily checked in the computer model of $V$ constructed via the code given in Chapter 2, as we just need to determine if a 16-regular graph on 252 vertices is connected (see Tables 2.3 and 2.4). ☐

**Lemma 4.2.6.** Suppose there are no quads in $S'$ that contain a point of $S$. Then the following holds:

1. every point of $\Gamma_1(S)$ in $S'$ is incident with precisely nine lines, exactly one of which intersects $S$;
2. if $x$ is a point of $\Gamma_1(S)$ and $L_1, \ldots, L_8$ are the eight lines of type CCC through $x$, then the $\mathcal{V}$-lines $\psi(L_1), \ldots, \psi(L_8)$ in $V$ are precisely the eight $\mathcal{V}$-lines of type CCC through $f_x$ (see Table 2.4);
3. every valuation of type $C$ is induced equally many times by the points of $\Gamma_1(S)$.

**Proof.** (1) Let $x$ be a point of $\Gamma_1(S)$ and $x'$ the unique point of $S$ which is collinear with $x$. Let $Y$ denote the set of neighbors of $x$ which do not lie on the line $xx'$. For any $y \in Y$, let $y'$ denote the unique point of $S$ collinear with $y$. The point $y'$, for any given $y \in Y$, must be noncollinear with $x'$ as otherwise $x'$ and $y$ will have two common neighbors giving rise to a quad in $S'$ which intersects $S$. Let $Y'$ denote the set of all points of $\Gamma_2(x) \cap S$ which are non-collinear with $x'$. Then we have shown that $y' \in Y'$ for all $y \in Y$.

The points of $\Gamma_2(x) \cap S$ are precisely those points of $S$ that have $f_x$-value 1, and by Table 2.3 there are precisely 22 of them. Out of these 22, 6 are neighbors of $x'$ and hence $|Y'| = 16$. We now show that the map $\varphi : Y \mapsto Y'$ where $\varphi(y) = y'$ is a bijection.

For every $z \in Y'$, there exists a unique common neighbor $y$ of $x$ and $z$, since if there are more than one, then we will get a quad intersecting $S$. This $y$ cannot lie in $S$ since otherwise it will coincide with the unique neighbor of $x$ in $S$, the point $x'$, which will contradict the fact that the points of $Y'$ are noncollinear with $x'$. Therefore, $\varphi$ is a bijection. This proves that $|Y| = 16$ and thus the total number of lines of type CCC through $x$ (which are precisely the lines through $x$ which do not intersect $S$) is equal to $|Y|/2 = 8$. Hence, there are 9 lines through $x$, exactly one of which, the line of type ACC, intersects $S$.

(2) If $y_1, y_2 \in Y$ with $y_1 \neq y_2$, then $f_{y_1} \neq f_{y_2}$, since $O_{f_{y_1}} \neq O_{f_{y_2}}$. Therefore, all points of the 8 lines of type CCC through $x$ induce distinct valuations of type $C$. This gives rise to 8 distinct $V$-lines of type CCC through the valuation $f_x$. By Table 2.4, these are all the type CCC lines of $V$ through $f_x$.

(3) In view of Lemma 4.2.5, it suffices to prove that for any two type $C$ valuations $f_1$ and $f_2$ which are collinear in $V$, the number of times $f_1$ is induced by a point of $S'$ is equal to the number of times $f_2$ is induced. This follows directly from (2), as for
every point $x$ for which $f_x = f_1$, there is a unique point $y$ for which $f_y = f_2$, and vice versa.

**Corollary 4.2.7.** Every generalized hexagon containing $S \cong H(2)^D$ as a full subgeometry is finite.

**Proof.** Let $S'$ be such a generalized hexagon. Then by Lemma 1.2.6, $S'$ is also thick, and hence has an order. Therefore, it suffices to show that there exists a point in $S'$ through which there are only finitely many lines. By Lemma 1.2.5, $S$ is isometrically embedded in $S$. Since there are no quads in a generalized hexagon, we see that every point of $\Gamma_1(S)$ has exactly nine lines through it, and thus $S'$ is finite. □

Lemma 4.2.6(3) shows that the map $\psi$ when restricted to the points of $S'$ is a surjection between the set of points of $S'$ and the valuations of $S$ that have type $A$ or $C$. Moreover, if there are no quads intersecting $S$, then the preimage of each valuation under this map has exactly $k$ elements for some constant $k$. Clearly this condition is satisfied if $S'$ is a generalized hexagon, which does not have any quads. We will now show that in general $S'$ does not have any quads that intersect $S$, from which we will later deduce that $S'$ is a generalized hexagon.

We already know of one generalized hexagon which contains $S \cong H(2)^D$ as a full proper subgeometry, the dual twisted triality hexagon $T(2,8)$. From Proposition 1.2.4, $T(2,8)$ has $819 = 63 + 3 \cdot 252$ points. Since there are precisely $252$ type $C$ valuations in $V$, from the discussion so far we deduce that every type $C$ valuation is induced exactly 3 times in $T(2,8)$. This embedding of $H(2)^D$ in $T(2,8)$ can now further help us in obtaining certain properties of the valuation geometry $V$ which will be useful to us. These properties can alternatively be checked in the computer model of $V$.

**Lemma 4.2.8.** Let $V'$ be the subgeometry of $V$ obtained by taking only points of type $C$ and the lines of type $CCC$. Then the following holds.

1. If $f_1, f_2$ are distinct collinear points of $V'$, then the unique points in $O_{f_1}$ and $O_{f_2}$ are at distance 3 from each other.

2. Suppose $G$ is a $(3 \times 3)$-subgrid of $V'$. Let $f_1, f_2$ be two noncollinear points of $G$ and for $i \in \{1,2\}$, let $x_i$ denote the unique point of $S$ in $O_{f_i}$. Then $x_1, x_2$ are distinct and $d(x_1, x_2) = 3$.

**Proof.** Just for the scope of this proof, let $S' \cong T(2,8)$.

1. Let $f_1, f_2$ be two distinct collinear points of $V'$. We know that the map $\psi$ in this case is surjective, and therefore we can pick two collinear type $C$ points $x_1, x_2$ in $S'$ such that $f_1 = f_{x_1}$ and $f_2 = f_{x_2}$. Let $x'_1$ and $x'_2$ be the unique points of $S \cong H(2)^D$ collinear with $x_1$ and $x_2$, respectively. Then we have $\{x'_1\} = O_{f_1}$ and $\{x'_2\} = O_{f_2}$. The distance between $x'_1$ and $x'_2$ must be at least 3 as otherwise we will get an ordinary $m$-gon for $m < 6$. Therefore, $d(x'_1, x'_2) = 3$.

2. The fact that $d(x_1, x_2) \geq 2$ follows from a similar reasoning as (1) inside $S' \cong T(2,8)$. To prove that the points are in fact at distance 3 from each other, we use the computer model of $V$ as we cannot find an easy argument using $T(2,8)$ which shows this. (Computationally we can see that if $f_1$ and $f_2$ are any two non-collinear points of $V'$ which have a common neighbor, then it is not necessarily true that $d(x_1, x_2) = 3$.)
Lemma 4.2.9. There are no quads in $S'$ which contain a point of $S$.

Proof. Let $Q$ be a quad in $S'$ which contains a point of $S$. Since $Q$ has three points on each line, we can find a $(3 \times 3)$-subgrid $G$ which also contains a point of $S$. Therefore we have two subspaces of $S'$, the grid $G$ and the subhexagon $S$, which intersect non-trivially. The intersection $G \cap S$ must also be a subspace and thus we have the following cases.

1. The grid $G$ is completely contained in $S$, which is impossible since $S$ is a generalized hexagon.

2. $G$ intersects $S$ in a union $L_1 \cup L_2$ of two intersecting lines. But then, any point of $G \setminus (L_1 \cup L_2)$, which is necessarily in $\Gamma_1(S)$ and of type $C$, will be collinear with two points of $S$, a contradiction to Lemma 4.2.2.

3. $G$ intersects $S$ in 2 or 3 mutually non-collinear points. Then take a common neighbor of any two points in $G \cap S$. Just like in (2), this gives us a contradiction as this point is collinear with at least two points of $S$.

4. $G$ intersects $S$ in a line $L$. Take a line $L'$ of $G$ which is disjoint from $L$. Take two points $x_1$ and $x_2$ on $L$, necessarily of type $C$, and let $y_1$ and $y_2$ be the unique points of $L$ collinear with $x_1$ and $x_2$, respectively. Then $f_{x_1}$ and $f_{x_2}$ are two distinct type $C$ valuations of $S$ for which the unique points in $\mathcal{O}_{f_{x_1}}$ and $\mathcal{O}_{f_{x_2}}$ are collinear, contradicting Lemma 4.2.8(1).

5. $G$ intersects $S$ in a point $x$. We label the points of $G$ by $x_{ij}$, $i, j \in \{1, 2, 3\}$, such that $x = x_{33}$ and $x_{ij}$ is collinear with $x_{i'j'}$ if and only if either $i = i'$ or $j = j'$ (see Figure 4.1). Let $f_{ij}$ denote the valuation induced by the point $x_{ij}$ of the grid. Then by a direct reasoning in $T(2,8)$, we must have $f_{31} = f_{23}$ and $f_{31} = f_{13}$. Which means that in the line $\{x_{13}, x_{23}, x_{33}\}$ of $S'$, we have $f_{13} = f_{23}$, contradicting Theorem 2.3.2.

Corollary 4.2.10. Every point of $S'$ not contained in $S$ is incident with precisely nine lines.

Proof. This follows from Lemmas 4.2.6 and 4.2.9.
One way to proceed now would be to directly show that there are no quads in \( S' \), but this seems to be difficult. We proceed indirectly by first proving that every point of \( S' \) is incident with precisely 9 lines.

**Lemma 4.2.11.** Let \( x \) be a point of \( S' \) not contained in \( S \), let \( x' \) be the unique point of \( S \) collinear with \( x \) and let \( y \) be a point of \( S \) which is at distance 2 from \( x' \). Then \( d(x, y) = 3 \) and every neighbor of \( y \) has at most one common neighbor with \( x \).

**Proof.** Let \( u \) denote the unique common neighbor of \( x' \) and \( y \), which necessarily lies in \( S \) by Lemma 4.2.2(3). Then \( d(x, u) = 2 \). If \( d(x, y) \neq 3 \), i.e., \( d(x, y) \leq 2 \), then \( \text{NP2} \) would imply that the line \( uy \) contains a point at distance 1 from \( x \), contradicting the fact that \( O_{f_x} \) is a singleton (see again Lemma 4.2.2(3)).

Now let \( z \) be a neighbor of \( y \) such that \( x \) and \( z \) have more than one common neighbor. Then by Theorem 1.3.8 there exists a quad \( Q \), and thus a \((3 \times 3)\)-subgrid \( G \), through \( x \) and \( z \). By Lemma 4.2.9 we have \( Q \cap S = G \cap S = \emptyset \), and in particular \( z \) lies outside \( S \). If two points of \( Q \) induce the same valuation, then they would have a common neighbor in \( S \) which by the convexity of \( Q \) would lie in \( Q \), thus contradicting Lemma 4.2.9. Therefore, each of the 9 points in \( G \) induce distinct type \( C \) valuations, and hence \( G \) induces a grid \( G' \) in the subgeometry \( \mathcal{V}' \) of \( \mathcal{V} \) formed by taking type \( C \) points and type \( CCC \) lines. Since \( x, z \) are noncollinear in \( G \), \( f_x, f_z \) are noncollinear in \( \mathcal{V}' \). We now get a contradiction to Lemma 4.2.8(2) because \( O_{f_x} = \{x'\} \), \( O_{f_z} = \{y\} \) and \( d(x', y) = 2 \). □

**Lemma 4.2.12.** Every point of \( S \) is incident with exactly 9 lines in \( S \), and hence \( S' \) has order \((2, 8)\).

**Proof.** Let \( x \) be a point of \( S \) and \( y \) another point of \( S \) at distance 2 from \( x \). Let \( f \) be a valuation of type \( C \) for which \( O_f = \{y\} \) (such a valuation always exists). Then by Lemma 4.2.6(3), there exists a point \( z \) in \( S' \) such that \( f_z = f \). This point \( z \) is collinear with \( y \).

By Lemma 4.2.11 \( d(z, x) = 3 \). We will show that there is a bijection between the lines through \( z \) (there are exactly 9 of them by Lemma 4.2.6) and the lines through \( x \).

We count the number of paths \( z, u, v, x \) of length 3 between \( z \) and \( x \). On each of the 9 lines through \( z \), by \( \text{NP2} \), there exists a unique point of \( \Gamma_2(x) \), and therefore there are 9 possibilities for \( u \). Since there are no quads through \( x \), every point of \( \Gamma_1(z) \cap \Gamma_2(x) \) has a unique common neighbor with \( x \). Therefore, for each of the 9 possibilities for \( u \), there is a unique possibility for \( v \), giving rise to exactly 9 such paths. Now let \( t_x + 1 \) be the (possibly infinite) number of lines through \( x \). Each such line contains a unique point at distance 2 from \( z \), giving rise to \( t_x + 1 \) choices for \( v \). By Lemma 4.2.11 for each such \( v \) there is a unique \( u \) (which is a common neighbor of \( z \) and \( v \)). Therefore the number of such paths is \( t_x + 1 \), and hence \( t_x + 1 = 9 \). □

Now Theorem 4.2.12 can be proved as follows. The total number of points in \( S' \) is \(|S| + 12 \cdot |S| = 63 + 12 \cdot 63 = 819 \) since each point of \( S \) is incident with precisely 6 lines of type \( ACC \), each of which gives rise to 2 points of \( S' \) not contained in \( S \) and this covers all points of \( S' \) by Lemma 4.2.2. It now follows from Lemma 1.3.6 that \( S' \) is a generalized hexagon of order \((2, 8)\) as \( 819 = (1 + 2)(1 + 2 \cdot 8 + 2^2 \cdot 8^2) \). This generalized hexagon is necessarily isomorphic to \( T(2, 8) \) by [53].

Page 52
4.2.2. Near Hexagons Containing $H(2)$

For this section, let $S'$ be a near hexagon with three points on each line which contains $S \cong H(2)$ isometrically embedded in it as a full subgeometry. We will use the same convention as before in assigning types to the points and lines of $S'$ based on the types in the valuation geometry of $H(2)$ (see Tables 2.5 and 2.6). Again from the basic theory of valuations we see that every point of $S'$ has one of the 7 types mentioned in Table 2.5 and every line has one of the 20 types mentioned in Table 2.6. Note that the type $C$ valuation is ovoidal.

Lemma 4.2.13. (1) Every point of $S'$ is at distance at most 2 from $S$.

(2) Every point $x$ of $S$ has type $A$, and the valuation $f_x$ is classical with center $x$.

(3) Every point of $S'$ at distance 1 from $S$ has type $B_i$ for some $i \in \{1, \ldots, 5\}$.

(4) Every point of $S'$ at distance 2 from $S$ has type $C$.

Proof. The proof is similar to Lemma 4.2.2, with the only complication occurring in the case when there is a point $x$ at distance 1 inducing a type $C$ (ovoidal) valuation. So let $x$ be such a point, and let $O = O_{f_x}$ be the ovoid of $S$ induced by points of $S$ that are collinear with $x$. We show that there exist two points in $O$ which are at distance 3 from each other, thus contradicting the assumption that $S$ is isometrically embedded in $S'$.

Let $y, z \in O$ such that $d(y, z) = 2$ (if no such pair exists, then there is nothing to prove). Let $w$ be their common neighbor in $S$. Since $O$ is a 1-ovoid, $w \not\in O$. Now let $w'$ be the third point on the line $wz$, and $L$ any line through $w'$ other than the line $wz$. Then $w' \not\in O$, and every point in $L \setminus \{w'\}$ has distance 3 from $y$ because $S$ is a generalized hexagon. At least one of the points in $L \setminus \{w'\}$ must be contained in $O$, giving us two points of $O$ at distance 3 from each other.

We can now prove (without invoking the classification result of [53]) that if $S'$ is a generalized hexagon then it must be equal to $S$, and in particular finite. We will give another proof of this result in Section 4.3.1.

Theorem 4.2.14. There exists no generalized hexagon which contains $H(2)$ as a full proper subgeometry.

Proof. Let $S'$ be a generalized hexagon containing $S \cong H(2)$ as a full subgeometry. By Lemma 4.2.6, it has an order $(2, t)$ where $t$ is a possibly infinite cardinal. We shall show that the only possible valuations of $S$ that points of $S'$ can induce are the type $A$ (classical) valuations, which by Lemma 4.2.13 would imply that $S' = S$. We do so in the following sequence of steps.

(1) There is no point in $S'$ of type $B_i$ with $i > 1$. Let $x$ be such a hypothetical point. By Lemma 4.2.13, $x$ must be at distance 1 from $S$. Since $|O_{f_x}| \geq 2$ (see Table 2.5), we can take two distinct points $y_1, y_2$ in $O_{f_x}$. These points are at distance 2 in $S'$ as $x$ is their common neighbor, and hence at distance 2 in $S$ because $S$ is isometrically embedded. Therefore, they have a common neighbor $y \not= x$ in $S$. This contradicts the fact that every pair of points at distance 2 in a generalized hexagon have a unique common neighbor.
There is no point in $S'$ of type $B_1$. Let $x$ be a point of type $B_1$ in $S'$. Then by Lemma 4.2.13, $x$ is at distance 1 from $S$ and since $\mathcal{O}_{f_x}$ is a singleton, there is a unique point $\pi(x)$ in $S$ collinear with $x$. The valuation $f_x$ has 22 points of value 1 (by Table 2.5) which by Theorem 2.2.3 is equivalent to the fact that there are exactly 22 points in $S$ which are at distance 2 from $x$. Out of these 22 points, 6 are neighbors of $\pi(x)$ in $S$ and therefore each of the remaining 16 must have a common neighbor with $x$ which lies outside $S$. Since $x$ is collinear with only type $B_1$ points in $\Gamma_1(S)$ (as by (1), there are no such points of type $B_i$ for $i > 2$ and by Lemma 4.2.13 there are no type $C$ points in $\Gamma_1(S)$), all of which have a unique neighbor in $S$, we get at least 16 points of type $B_1$ in $\Gamma_1(S)$ collinear with $x$. All of these neighbors of $x$ must induce distinct valuations since their zero sets ($\mathcal{O}_f$) are distinct. Therefore, we get 16 type $B_1$ neighbors of the valuation $f_x$ in the valuation geometry $V$, which contradicts the entry in row $B_1B_1B_1$ and column $B_1$ of Table 2.6 which says that there are only 6 such neighbors.

There is no point in $S'$ of type $C$. By Table 2.6, we see that every line through such a point must contain a point of type $B_i$ for some $i > 1$, but no such point exists by (1).

We now prove that every near hexagon $S'$ containing $S \cong \mathbb{H}(2)$ as a full isometrically embedded subgeometry is finite. The reasoning below gives an alternate proof of Theorem 4.2.14 if we invoke the classification of finite generalized hexagons with three points on each line and the observation that none of the hexagons appearing in the classification contain $\mathbb{H}(2)$ as a proper subgeometry. One of the main results we use in these proofs is Lemma 1.3.9 which in particular shows that every pair of points in $S'$ at distance 2 from each other have finitely many common neighbors.

**Lemma 4.2.15.** For every $i \in \{2, 3, 4, 5\}$ there are only finitely many points in $S'$ of type $B_i$.

**Proof.** Let $x$ be a point of type $B_i$ for some $i > 1$. From Table 2.5 there are at least two distinct points $y$ and $z$ of $S$ in $\mathcal{O}_{f_x}$, necessarily collinear with $x$. By NP2 $y$ and $z$ must be at distance 2 from each other. Now, $y$ and $z$ have at most five common neighbors (Lemma 1.3.9) and one of these must be contained in $S$. From this it follows that the number of points of type $B_i$ for some $i \in \{2, 3, 4, 5\}$ is at most 4 times the number of unordered pairs $\{p, q\}$ of points of $S$ at distance 2 from each other, which is finite (in fact equal to 3024).

**Lemma 4.2.16.** There are only finitely many points of type $B_1$ in $S'$.

**Proof.** Let $B$ denote the set of those points of $S'$ that have type $B_i$ for some $i \in \{2, 3, 4, 5\}$. Then $B$ is finite by Lemma 4.2.15. Let $A$ denote the set of those points of $S'$ that have type $A$, i.e., the points of $S$. Then the set $A \cup B$ is also finite. Let $x$ be a point of type $B_1$ in $S$. Then by Lemma 4.2.13, $x$ is at distance 1 from $S$, and since $\mathcal{O}_{f_x}$ is a singleton, there exists a unique point $\pi(x)$ in $S$ collinear with $x$. If $x$ is only collinear with points of type $A$, $B_1$ or $C$, then by the same reasoning as in the proof of Theorem 4.2.14 we get a contradiction. So, $x$ is collinear with at least one point of $B$, and we have already seen that it is collinear with at least one point of $A$. Thus we see that $x$ is the common neighbor of two points at distance 2 in the finite set $A \cup B$. Since each such pair of points at distance 2 in the near polygon $S'$ has finitely many (at most 5) common neighbors, we
see that the set of points of type $B_1$ must be finite; in fact, the cardinality of this set is bounded above by 5 times the number of pairs of points at distance 2 in $A \cup B$.

**Lemma 4.2.17.** There are only finitely many points of type $C$ in $S'$.

**Proof.** Let $x$ be a point of type $C$ in $S'$. Then the set $\Gamma_2(x) \cap S$ is a 1-ovoid of $S$, and hence it has cardinality 21. Let $S_x$ be the set of common neighbors between $x$ and elements of $O_f$ (the 1-ovoid of $S$ induced by $x$). By Lemma 4.2.13 each element $y$ of $S_x$ has type $B_i$ for some $i \in \{1, \ldots, 5\}$ and hence by Table 2.5 $y$ is collinear with at most 9 points of $S$. Therefore $|S_x| \geq 2$, and we get two points of the set $\Gamma_1(S)$ at distance 2 from each other having $x$ as a common neighbor. By Lemmas 4.2.15 and 4.2.16, the set $\Gamma_1(S)$ is finite, and thus by a same reasoning as before there are only finitely many points in $S'$ of type $C$. 

From Lemmas 4.2.15, 4.2.16 and 4.2.17 it follows that $S'$ must be finite. We finally note that there are near hexagons which are not generalized hexagons and contain $S \cong H(2)$ as a full isometrically embedded subgeometry, for example, the dual polar spaces $\text{DW}(5, 2)$ and $\text{DH}(5, 4)$

We do not provide any classification of these near hexagons.

### 4.3. Polygonal Valuations and Intersections of Hyperplanes

While the theory of valuations outlined in Chapter 2 works quite well for near polygons with three points on each line, for other near polygons it is difficult in practice. Firstly, in the case when there are more than three points on a line, we do not have a good way of computing hyperplanes; and thus the approach outlined in Section 3.4 does not work. So, we might have to stick to a direct backtrack search to find all the valuations, which will only work for really small cases. Second, we lose the power of Theorem 2.3.2 which lets us define the valuation geometry by simply taking pairs of distinct neighboring valuations, instead of arbitrary triples of pairwise neighboring valuations.

In this section, we will give a short summary of the theory of so-called *polygonal valuations* (developed by De Bruyn in [60]) which is more restrictive than the one specified in Chapter 2 and only suitable to study generalized polygons containing a subpolygon. This theory will be used to derive some counting based results on intersections of hyperplanes in arbitrary generalized hexagons with an order (Lemma 4.3.7), which will help us prove some results for generalized hexagons containing $H(3)$, $H(4)$ or $H(4)^D$ as a full subgeometry (Theorem 4.3.11). Note that in contrast with Section 4.2 we will not be able to say anything about near hexagons which are not generalized hexagons and contain these subhexagons.

**Definition.** Suppose $S = (P, L, I)$ is a generalized $2n$-gon with $n \in \mathbb{N} \setminus \{0, 1\}$. Then a *polygonal valuation* of $S$ is a map $f : P \to \mathbb{N}$ that satisfies the following axioms:

- **(PV1)** There exists at least one point with $f$-value 0.
- **(PV2)** Every line $L$ of $S$ contains a unique point $x_L$ such that $f(x) = f(x_L) + 1$ for all points $x \neq x_L$ incident with $L$.

\(^1\)In fact, this kind of explains why the valuation geometry of $H(2)$ is much larger than that of $H(2)^D$. 

---

**Page 55**
(PV3) Let $M_f$ denote the maximum value of $f$ over the points of $S$. If $x$ is a point with $f(x) < M_f$, then there is at most one line through $x$ containing a (necessarily unique) point $y$ satisfying $f(y) = f(x) - 1$.

Or in other words, a polygonal valuation is a valuation of $S$ which satisfies the condition (PV3). It turns out that with this one extra condition, we have a much stronger theory where several interesting and new results hold. For example, from the following result it follows that the polygonal valuations of a generalized polygon are in bijective correspondence with its hyperplanes of valuation type.

Lemma 4.3.1 ([60, Proposition 3.10]). If $f$ is a polygonal valuation of a generalized $2n$-gon $S = (P, L, I)$, then $f(x) = M_f - d(x, P \setminus H_f)$ for every point $x$ of $S$, where $H_f$ is the hyperplane of $S$ corresponding to $f$.

It is easy to check that the classical, semi-classical and ovoidal valuations defined in Chapter 2 all satisfy (PV3). And hence, these are all examples of polygonal valuations as well. In fact, for generalized hexagons these are the only possible polygonal valuations, as the following lemma shows.

Lemma 4.3.2 ([60, Proposition 3.3]). Suppose $f$ is a polygonal valuation of a generalized $2n$-gon $S$. Then:

1. $f$ is an ovoidal polygonal valuation if and only if $M_f = 1$;
2. $f$ is a semi-classical polygonal valuation if and only if $M_f = n - 1$;
3. $f$ is a classical valuation if and only if $M_f = n$.

Corollary 4.3.3. If $S$ is a generalized hexagon, then every polygonal valuation of $S$ is classical, semi-classical or ovoidal.

Proof. As noted in Section 2.2, the maximum value of a valuation (and hence a polygonal valuation) is bounded above by the diameter of the near polygon. Therefore, for any polygonal valuation $f$ of a generalized hexagon, we have $M_f \in \{1, 2, 3\}$.

A quick glance at Table 2.3 of Chapter 3 will show that Corollary 4.3.3 does not hold for valuations of near hexagons, as the type $B$ and type $D$ valuations are not classical, semi-classical or ovoidal. Since we know how to compute these three types of valuations, we can use the machinery of Chapter 3 to find out all polygonal valuations of generalized hexagons (even those which have more than three points on each line). We now state the analogous result of Theorem 2.2.3 for polygonal valuations.

Lemma 4.3.4 ([60, Proposition 6.1]). Let $S = (P, L, I)$ be a generalized $2n$-gon contained in a generalized $2n$-gon $S' = (P', L', I')$ as a full subgeometry. Let $x$ be a point of $S'$ and put $m := d(x, P)$. Noting that $m \in \{0, 1, \ldots, n - 1\}$, we define $f_x(y) := d(x, y) - m$ for every point $y \in P$. Then:

1. $f_x$ is a valuation of $S$ with $M_{f_x} = n - m$.
2. The valuation $f_x$ is classical if and only if $x$ is a point of $S$, semi-classical if and only if $m = 1$ and ovoidal if and only if $m = n - 1$.
3. If $x_1$ and $x_2$ are two distinct collinear points of $S$, then the valuations $f_{x_1}$ and $f_{x_2}$ are distinct.
For a result analogous to Theorem 2.2.6, we define the notion of \( L \)-sets and admissible sets of polygonal valuations of a generalized 2\( n \)-gon \( S \), which will correspond to the lines of a generalized 2\( n \)-gons containing \( S \) as a full subgeometry. This notion will also allow us to define the notion of polygonal valuation geometry, that is useful in classifying generalized polygons containing a fixed subpolygon.

**Definition.** Let \( S = (P, L, I) \) be a generalized 2\( n \)-gon. A collection \( F = \{ f_i : i \in I \} \) of distinct polygonal valuations of \( S \), where \( I \) is an index set of cardinality at least 2, is called an \( L \)-set if for every \( x \in \mathcal{P} \), there exists an \( i \in I \) such that \( f_j(x) - M_{f_i} = f_i(x) - M_{f_j} + 1 \) for every \( j \in I \setminus \{ i \} \). The set \( F \) is called admissible if the following holds for all \( i, j \in I \) with \( i \neq j \), for all \( x \in \mathcal{P} \) such that \( x \) is not collinear with any point with \( f_i \)-value \( f_i(x) - 1 \), and for all \( y \in \mathcal{P} \) such that \( y \) is not collinear with any point with \( f_j \)-value \( f_j(y) - 1 \):

1. if \( f_i \) and \( f_j \) are classical, then \( d(x, y) = 1 \);
2. if \( x = y \), then \( (f_i(x) - M_{f_i}) - (f_j(x) - M_{f_j}) \in \{-1, 0, 1\} \);
3. if \( x \neq y \) and at least one of \( f_i, f_j \) is not classical, then \( d(x, y) + f_i(x) + f_j(y) - M_{f_i} - M_{f_j} + 1 \geq 0 \).

**Lemma 4.3.5** ([60 Proposition 6.2]). Let \( S \) be a generalized 2\( n \)-gon contained in a generalized 2\( n \)-gon \( S' \) as a full subgeometry. For every line \( L \) of \( S' \) define \( F_L = \{ f_x : x \in L \} \), where \( f_x \) denotes the valuation of \( S \) induced by the point \( x \). Then \( F_L \) is an admissible \( L \)-set of polygonal valuations.

**Definition.** The polygonal valuation geometry of a generalized 2\( n \)-gon \( S \) is the point-line geometry \( \mathcal{V}_S \) whose points are the polygonal valuations of \( S \) and lines are the admissible \( L \)-sets of polygonal valuations of \( S \), with incidence as set containment.

Just like the notion of valuation geometry defined in Chapter 2 for near polygons with three points on each line, this notion of polygonal valuation geometry for generalized polygons (with any number of lines per point) can help us study generalized polygons containing a fixed generalized polygon as a full subgeometry. This is precisely what was used by De Bruyn in [62] to prove that there is a unique generalized octagon of order \((2, 4)\) containing a suboctagon of order \((2, 1)\). In fact, polygonal valuation geometry of the split Cayley hexagon \( H(3, 1) \) (which is not too hard to compute using the tools described in Chapter 3) can be used to prove the result of De Medts and Van Maldeghem [67] that \( H(3) \) is the unique generalized hexagon containing a subhexagon of order \((3, 1)\). This is an unpublished proof by De Bruyn which was mentioned in [61]. For our purposes, we do not need the full power of polygonal valuation geometry, but only the following result on hyperplanes that follows directly from Lemma 4.3.5 and [60 Proposition 4.7], and its consequences.

**Lemma 4.3.6.** Let \( S = (P, L, I) \) be a generalized 2\( n \)-gon contained in a generalized 2\( n \)-gon \( S' = (P', L', I') \) as a full subgeometry, and let \( L \) be a line of \( S' \). For a point \( x \) of \( S' \), let \( H_x \) denote the hyperplane of \( S \) formed by points of \( S \) at distance at most \( n - 1 \) from \( x \). Then:

1. the set of hyperplanes \( \{ H_x : x \in P', x \not\in L \} \) covers \( P \);
2. if \( x_1, x_2 \) and \( x_3 \) are three distinct points on \( L \), then \( H_{x_1} \cap H_{x_2} = H_{x_1} \cap H_{x_3} \).
A finite generalized hexagon of order \((s, t)\) has \((1 + s)(1 + st + s^2t^2)\) points. For each of the three types of hyperplanes in generalized hexagons corresponding to the three types of polygonal valuations, we can determine the sizes of the hyperplanes by simple counting. The singular, semi-singular and ovoidal hyperplanes in a finite generalized hexagon of order \((s, t)\) are of sizes \(1 + s(t + 1) + s^2t(t + 1), 1 + s(t + 1) + s^2t^2\) and \(1 + st + s^2t^2\) respectively. The following is the main result on hyperplane intersections that we will use to prove Theorem 4.3.11.

**Lemma 4.3.7.** Let \(S\) be a finite generalized hexagon of order \((s, t)\) containing a subhexagon \(S'\) as a full subgeometry, and let \(L\) be a line of \(S'\) that does not intersect \(S\). Let \(n_L\) denote the number of points on \(L\) that are at distance 2 from \(S\). For a point \(x\) in \(S'\), let \(H_x\) denote the hyperplane of \(S\) formed by taking points of \(S\) that are at non-maximal distance from \(x\). Then for any two distinct points \(x\) and \(y\) on \(L\) we have \(|H_x \cap H_y| = s + 1 - n_L|\).

**Proof.** By Lemma 4.3.4 and the fact that opposite lines are incident with the same number of points, we know that every line of \(S'\) is incident with precisely \(s + 1\) points. By Lemma 4.3.4 for every point \(x\) on \(L\) the hyperplane \(H_x\) of \(S\) is either semi-singular or ovoidal. The points on \(L\) that are at distance 1 from \(S\) induce semi-singular hyperplanes, while those at distance 2 induce ovoidal hyperplanes. By Lemma 4.3.6 there exists a fixed subset \(X\) of points of \(S\) such that \(H_x \cap H_y = X\) for every pair of distinct points \(x, y\) on \(L\), and every point of \(S\) is contained in some hyperplane induced by a point on \(L\). Let the size of \(X\) be \(k\). There are \(n_L\) hyperplanes of size \(1 + st + s^2t^2\) (ovoidal) and \(s + 1 - n_L\) hyperplanes of size \(1 + s(t + 1) + s^2t^2\) (semi-singular) which cover a set of size \((1 + s)(1 + st + s^2t^2)\) (points of \(S\)) and pairwise intersect in \(k\) points. Therefore, we have

\[
n_L(1 + st + s^2t^2 - k) + (s + 1 - n_L)(1 + s(t + 1) + s^2t^2 - k) + k = (1 + s)(1 + st + s^2t^2),
\]

which can be solved for \(k\) to get \(k = s + 1 - n_L|\). □

**Lemma 4.3.8.** Let \(S\) be a finite generalized hexagon of order \((s, t)\) having the property that \(|H_1 \cap H_2| > s + 1\) for any two semi-singular hyperplanes \(H_1\) and \(H_2\) of \(S\) whose centers lie at distance 3 from each other. Then there does not exist any generalized hexagon that contains \(S\) as a full proper subgeometry.

**Proof.** Say there is such a generalized hexagon \(S'\) and let \(x\) be a point of \(S'\) that is at distance 1 from the point set of \(S\). By Lemma 4.3.4 \(H_x\) is a semi-singular hyperplane, corresponding to the semi-classical polygonal valuation \(f_x\) defined by \(f_x(y) = d(x, y) - 1\) for points \(y\) of \(S\). Let \(x'\) be the unique point of \(S\) with \(f_x\)-value 0, or equivalently the unique point of \(S\) at distance 1 from \(x\). Let \(O'\) be the 1-ovoid in the subgeometry of \(S\) induced on \(\Gamma_3(x')\) which defines the hyperplane \(H_x\). Let \(y\) be a point of \(O'\). Then \(f_x(y) = 1\), and hence \(d(x, y) = 2\). Let \(z\) be a common neighbor of \(x\) and \(y\). Then \(z\) must lie outside \(S\), and the line \(L = xz\) does not contain any point of \(S\). Note that \(f_z\) is also a semi-classical polygonal valuation since \(z\) has distance 1 from \(S\). From Lemma 4.3.7 it follows that \(|H_x \cap H_z| \leq s + 1\). Moreover we have \(d(x', y) = 3\), thus contradicting the assumption stated in the lemma. □

We will use Lemma 4.3.8 to prove Theorem 4.3.11(2) in Section 4.3.1. The following result will help us prove the finiteness of generalized hexagons containing a subhexagon.

**Lemma 4.3.9.** Let \(S\) be a finite generalized hexagon with only thick lines that is contained in a generalized hexagon \(S'\) as a full subgeometry. If every point of \(S'\) is at distance at most 1 from \(S\), then \(S'\) is also finite.
Proof. Lemma 1.2.6 implies that every line of $S'$ is also thick and hence has an order. Suppose now that every point of $S'$ is at distance at most 1 from $S$ and that $S' \neq S$. Let $x$ be a point in $S'$ at distance 1 from $S$. Then it suffices to show that there are only finitely many lines through $x$.

Note that $x$ induces a semi-classical polygonal valuation on $S$, and thus there exists a unique point $y$ of $S$ with $f_x$-value 0, which by Lemma 4.3.4 is the unique point of $S$ at distance 1 from $x$. Therefore, there is a unique line through $x$ in $S'$ which meets $S$. Now, let $L$ be any other line through $x$. Pick any point $z$ in $L \setminus \{x\}$. Then $z$ is again collinear with a unique point $z'$ of $S$ as every point of $S'$, and in particular $z$, is at distance at most 1 from $S$. In this manner we can associate each line of $S'$ through $x$ that does not intersect $S$ with a point of $S$. Moreover, for two distinct lines $L_1, L_2$ through $x$ not meeting $S$ the points $z'_1, z'_2$ of $S$ obtained in this manner by taking points $z_1 \in L_1 \setminus \{x\}$ and $z_2 \in L_2 \setminus \{x\}$ must be distinct, as otherwise we will get a pair of points at distance 2 from each in the generalized hexagon $S'$ that have at least two common neighbors. Since the number of points in $S$ is finite, this shows that there are only finitely many lines through $x$. 

Corollary 4.3.10. If a generalized hexagon $S$ does not have any 1-ovoids, then it cannot be contained in a semi-finite generalized hexagon as a full subgeometry.

Proof. Let $S'$ be a generalized hexagon containing $S$ as a full subgeometry. Say $S$ does not have any 1-ovoid. Then by Lemma 4.3.4 every point of $S'$ is at distance at most 1 from $S$, and so $S'$ should be finite by Lemma 4.3.9. 

Remark. In [66], De Bruyn and Vanhove showed that no generalized hexagon of order $(s, s^3)$ can have 1-ovoids, thus proving that these hexagons cannot be contained in a semi-finite generalized hexagon as a full subgeometry (see Corollary 3.20 in [66]).

4.3.1. Generalized Hexagons Containing Split Cayley Hexagons and their Dual

We give a computer-aided proof of the following result in this section.

Theorem 4.3.11. Let $q \in \{2, 3, 4\}$ and let $S$ be a generalized hexagon isomorphic to the split Cayley hexagon $H(q)$ or its dual $H(q)^D$. Then the following holds for any generalized hexagon $S'$ that contains $S$ as a full subgeometry:

(1) $S'$ is finite;

(2) if $q \in \{2, 4\}$ and $S \cong H(q)$, then $S' = S$.

From Corollary 4.3.10 and the non-existence of 1-ovoids in $H(4)^D$ proved in Section 3.5 it follows that every generalized hexagon containing a subhexagon isomorphic to $H(4)^D$ is finite. The same holds for generalized hexagons containing $H(2)^D$ as by Table 2.3, it does not have any 1-ovoids.

Now let $S \cong H(3)$ and let $S'$ be a generalized hexagon containing $H(3)$ as a full subgeometry. Say there exists a point $x$ in $S'$ at distance 2 from $S$ and let $x, y, z$ be a path of length 2 from $x$ to a point $z$ of $S$. Then by Lemma 4.3.7 we have $|H_x \cap H_y| \leq 3$, where $H_x$ is the 1-ovoid of $S$ induced by $x$ and $H_y$ is the semi-singular hyperplane of $S$ induced by $y$. Note that $z \in H_x$ and $z$ is the center of $H_y$. Since the geometry is small enough and
the automorphism group acts transitively on the points, we can fix a point \( p \) of \( H(3) \) in our computer model obtained in Chapter 3 and look at the intersection sizes of 1-ovoids through \( p \) and semi-singular hyperplanes with center \( p \). The following SageMath code can be used for this computation. We assume that the SageMath function \texttt{ovoids} defined in Chapter 3 is available to us, and that the function \texttt{get_data} gives us the points, lines and the distance matrix of a point-line geometry (which can be implemented using the methods of Chapter 3).

\[
\text{def}\ \texttt{semi\_singular\_hyperplanes}(\texttt{points},\ \texttt{lines}, \ \texttt{D}, \ \texttt{p}): \nonumber
\]

\[
\text{""
Computes all semi-singular hyperplanes of a point line
geometry with a fixed point as center.

\textbf{Args:}
points -- a list of points
lines -- a list of lines
\texttt{D} -- the distance matrix of the collinearity graph
\texttt{p} -- the fixed point

\textbf{Returns:}
a list of all semi-singular hyperplanes with center \texttt{p}
""
\]

\[
\text{dist3} = [x \text{ for } x \text{ in } \texttt{points} \text{ if } \texttt{D}[x][\texttt{p}] == 3]
\]

\[
\text{L} = [l \text{ for } l \text{ in } \texttt{lines} \text{ if } \text{any}([x \text{ in } \texttt{dist3} \text{ for } x \text{ in } l])]
\]

\[
\text{L} = [[x \text{ for } x \text{ in } l \text{ if } x \text{ in } \texttt{dist3}] \text{ for } l \text{ in } \texttt{L}]
\]

\[
\text{ov} = \text{list}(\texttt{ovoids}(\texttt{dist3}, \texttt{L}))
\]

\[
\text{return} \ \text{[sorted([x \text{ for } x \text{ in } \texttt{points} \text{ if } x \text{ in } O \text{ or } \texttt{D}[x][\texttt{p}] <= 1}) \text{ for } O \text{ in } \texttt{ov}]}\]

\[
# \texttt{H(3)}
\]

\[
\text{points, lines, } \texttt{D} = \texttt{get\_data("H3")}
\]

\[
\text{p} = \text{points}[0]
\]

\[
\text{ovoids\_p} = [0 \text{ for } 0 \text{ in } \texttt{ovoids(points, lines) if } \texttt{p} \text{ in } 0]
\]

\[
\text{hyp\_p} = \texttt{semi\_singular\_hyperplanes}(\texttt{points}, \texttt{lines}, \texttt{D}, \texttt{p})
\]

\[
\text{S} = \{\text{len(set(x)} \ & \ \text{set(y)}) \text{ for } x \text{ in } \texttt{ovoids\_p} \text{ for } y \text{ in } \texttt{hyp\_p}\}
\]

\[
\text{print } \text{"Check }\texttt{H(3): "} + \text{str}(\text{min(S)} > 3)
\]

We find that every pair of ovoidal and semi-singular hyperplane of \( H(3) \) through a fixed point which is also the center of the semi-singular hyperplane intersect in more than 3 points. Therefore, every point of \( S \) must be at distance at most 1 from \( S \). Then it follows from Lemma 4.3.9 that \( S \) is finite.

Finally, let \( S \) be isomorphic to \( H(2) \) or \( H(4) \) and let \( q \) be the order of \( S \). By Lemma 4.3.8 to show that \( S \) cannot be embedded in any generalized hexagon as a proper full subgeometry, it suffices to check that for every pair of points \( x_1, x_2 \in S \) at distance 3 from each other and for every pair of semi-singular hyperplanes \( H_1, H_2 \) with respective centers \( x_1 \) and \( x_2 \), we have \( |H_1 \cap H_2| > q + 1 \). This can be checked using the following SageMath code. Note that by distance transitivity of the automorphism group we only need to check this for one pair of points at distance 3 from each other, thus reducing the amount of computations.
Remark. Generalized hexagons of order greater than 4 seem to be out of reach with our computational methods. And we do not know of any results on intersection sizes of semi-singular and ovoidal hyperplanes of split Cayley hexagons that can help us obtain the above results in general. It would be nice to be able to prove that for all prime powers $q = p^r$, with $p \neq 3$ prime, every pair of semi-singular hyperplanes in $H(q)$ whose centers are at maximum distance 3 intersect in more than $q + 1$ points, which will then imply that these generalized hexagons cannot be contained in bigger generalized hexagons as full subgeometries.
5. Two New Near Octagons

5.1. Introduction

The well-known Hall-Janko near octagon \( HJ \) was constructed by Cohen in [52] as the point-line geometry formed by taking a particular conjugacy class \( C \) of 315 involutions in the Hall-Janko group \( J_2 \) as points, and the sets \( \{x, y, xy\} \) where \( x, y \in C \) are distinct commuting involutions as lines. This is a regular near octagon of order \((2^4, 0; 3^3)\) (see Section 1.3) and has automorphism group isomorphic to \( J_2:2 \) (the split extension of \( J_2 \) by the cyclic group \( C_2 \)) acting primitively and distance-transitively on the points. A detailed study of this geometry was done by Yoshiara in [142] where in particular it was shown that \( HJ \) contains \( H(2)^D \) (and \( GO(2, 1) \)) as convex subgeometries. Thus it is natural to wonder whether \( HJ \) is the unique near octagon of order \((2^4, 0; 3^3)\) which contains \( H(2)^D \) as a full isometrically embedded subgeometry. We address this in Chapter 6 where we give a proof of this fact using the valuation geometry of \( H(2)^D \). In this chapter, we will see how valuation geometries can sometimes give rise to new “interesting” near polygons.

The valuation geometry of \( HJ \) is described in Tables 2.7 and 2.8. It is easy to see from the tables that if we take valuations of type \( A \), \( B \) and \( C \) as points, and all valuation lines of type \( AAA \), \( ABB \), \( ACC \), \( BBC \) and \( CCC \) as lines (so we skip the valuation lines of type \( BBB \)), then we get a partial linear space of order \((2^{10}) \) on \( 4095 \) points. Using a computer model of this partial linear space, it can be easily checked that this is in fact a near octagon. Moreover, computations in SageMath show that the automorphism group \( G \) of this near octagon has the following properties:

- \( G \) acts transitively on the points;
- \( |G| = 503193600 \);
- the derived subgroup \( G' \) is a simple group of size 251596800.

These properties suggest that \( G \) is isomorphic to the group \( G_2(4):2 \) (see [54]), which is also the automorphism group of the split Cayley hexagon \( H(4) \). We give an alternate construction of this near octagon by directly using the group \( G_2(4):2 \), which is similar to the construction of \( HJ \) given above. This construction will allow us to give a computer-free proof of the fact that the automorphism group of this near octagon is indeed isomorphic to \( G_2(4):2 \), and help us obtain several useful properties. Recall that a line spread of a partial linear space is a set of lines which covers each point exactly once.

**Theorem 5.1.1.** (1) Let \( O_1 \) be the point-line geometry whose points are the 4095 central involutions \(^1\) of the group \( G = G_2(4):2 \) and whose lines are all the three element subsets \( \{x, y, xy\} \) where \( x, y \) are two commuting central involutions that satisfy \( |G :
Theorem 5.1.2. (1) Let $O_2$ be the point-line geometry whose points are the 315 central involutions of the group $G = L_3(4):2^3$ and whose lines are all the three element subsets $\{x, y, xy\}$ where $x, y$ are two commuting central involutions $x, y$ that satisfy $[G : N_G((x,y))] = 105$, with incidence being containment. Then $O_2$ is a near octagon of order $(2, 4)$. 

(2) Let $S_2$ denote the set of all lines $\{x, y, xy\}$ where $x$ and $y$ are two commuting central involutions that satisfy $[G : N_G((x,y))] = 1365$. Then $S_2$ is a line spread of $O_2$. If $Q_2$ denotes the set of all quads of $O_2$, then for every $Q \in Q_2$ the lines of $S_2$ contained in $Q$ define a line spread of $Q$. Moreover, the point-line geometry $S_2$ with point set $S_2$, line set $Q_2$ and incidence as set containment, is isomorphic to the unique generalized hexagon isomorphic to the dual split Cayley hexagon $H(4)^D$.

The near octagons $O_1$ and $O_2$ will be called the “$G_2(4)$ near octagon” and the “$L_3(4)$ near octagon”, respectively. We will prove Theorems 5.1.1(1) and 5.1.2(1) in Section 5.2. The structure of these near octagons around a fixed point can be described by a diagram (see Figures 5.1 and 5.2). These two diagrams are very similar and in Section 5.3 we study geometric properties of a family of near octagons whose local structures can be described by such diagrams. Part (2) of Theorems 5.1.1 and 5.1.2 will follow from that discussion. At this moment, we do not know whether the $G_2(4)$ and $L_3(4)$ near octagons are the only nontrival members of this family of near octagons. In Section 5.4 we study the suboctagons of $O_1$ which are isomorphic to $HJ$, proving that there are 416 such suboctagons of $O_1$. We also prove some properties of these suboctagons which will be useful later in Section 5.5 and Chapter 6. Moreover, using these suboctagons we give a new proof of the result of De Wispelaere and Van Maldeghem [70], that $HJ^D$ as a full embedding in the split Cayley hexagon $H(4)$. In Section 5.5 we determine the full automorphism group of the near octagons $O_1$ and $O_2$.

Theorem 5.1.3. The automorphism groups of the $G_2(4)$ near octagon and the $L_3(4)$ near octagon are isomorphic to $G_2(4):2$ and $L_3(4):2^2$, respectively.

\footnote{It is also standard to denote the group $L_3(4)$ by $PSL_3(4)$, but we will follow the convention of referring to it as $L_3(4)$.}
Finally, in Section 5.6 we describe the connection between these near octagons and the distance regular graphs discovered by Soicher in [129], which also gives alternate constructions for these geometries.

Remark. In general, it is hard to construct new “nice near polygons”, for example point-transitive near polygons which are not bipartite graphs. Besides some infinite families (the most recent one being discovered around 15 years ago [56]), there are some examples related to sporadic simple groups which were discovered around 1980 [7], [52], [126]. We hope that our two near polygons may lead to the discovery of some more new “nice near polygons” (for example, by similar constructions using some other group actions).

5.2. Suborbit Diagrams

5.2.1. The $G_2(4)$ Near Octagon

The group $G = G_2(4):2$ has precisely three conjugacy classes of involutions (see [54]). The class $2A$ consists of 4095 involutions all of which are central and contained in the derived subgroup $G' \cong G_2(4)$. A computer model of the group $G$ can be easily constructed using the computer algebra system GAP. All group theoretical claims of the present section have been verified using such a computer model.

Let $P$ denote the set of all 4095 central involutions of $G$. The group $G$ acts on $P$ by conjugation ($x \mapsto x^g = g^{-1}xg$). Let $\omega$ denote a fixed central involution of $G$. The stabilizer $G_\omega$ of $\omega$ has eight orbits on $P$, the so-called suborbits of $G$ with respect to $\omega$. Such a suborbit will be denoted by $O_0$, $O_{1a}$, $O_{1b}$, $O_{2a}$, $O_{2b}$, $O_{3a}$, $O_{3b}$ and $O_4$ in accordance with the information provided by Table 5.1. In the table, we have mentioned the sizes of the suborbits and descriptions for the groups $\langle x, \omega \rangle$, where $x$ is an arbitrary element of the considered suborbit.

Table 5.1.: Suborbit description for $G_2(4):2$

The central involutions distinct from $\omega$ which commute with $\omega$ are those of the set $O_{1a} \cup O_{1b} \cup O_{2a}$. Moreover, if $O \in \{O_{1a}, O_{1b}, O_{2a}\}$ and $x \in O$, then $\omega x \in O$. The sets $O_{1a}$, $O_{1b}$ and $O_{2a}$ consist of those central involutions $x \neq \omega$ for which $[G : N_G(\langle x, \omega \rangle)]$ has size 1365, 13650 and 27300, respectively.

Let $L$ denote the set of all triples $\{x, y, xy\}$, where $x$ and $y$ are two distinct commuting central involutions such that $[G : N_G(\langle x, y \rangle)]$ has size 1365 or 13650 and let $O_1$ be the point-line geometry with point set $P$ and line set $L$, where incidence is containment. Using

---

In particular, we do not assume any background on Chevalley groups, as we simply obtain all the required properties of $G_2(4):2$ using elementary arguments along with computations in GAP, and the information given in ATLAS [54].
Two New Near Octagons

GAP we have computed the suborbit diagram for the central involutions of $G_2(4):2$, which is given in Figure 5.1. Each of the eight big nodes in Figure 5.1 denotes a suborbit and an edge between two such nodes denotes the property that there is a line that intersects both suborbits. A smaller node on each edge denotes a line and the two accompanying numbers denote the number of points of the line that lie in the suborbits it intersects. Each number on a big node denotes the number of lines through a given point in that suborbit going to another suborbit.

In the literature, suborbit diagrams for finite simple groups where adjacency (in the collinearity graph of the involution geometry) is defined by commutativity have been studied (see for example [16], [17] and [142]). For drawing our suborbit diagram(s) we have used similar conventions as in [16]. In our case adjacency involves both commutativity and a condition on the index of certain normalizers. As per [34, Page 397], “Sometimes pairs of commuting involutions from $D$ (where $D$ is a conjugacy class of involutions) fall into several $G$-orbitals; choosing one orbital for adjacency, one obtains commuting involutions graph in the wider sense”. Therefore, the collinearity graph of the point line geometry $O_1$ we have just constructed is a commuting involution graph in the wider sense; noting that we have chosen two suborbits (orbitals) instead of one to define adjacency.

**Theorem 5.2.1.** The point-line geometry $O_1$ is a near octagon of order $(2, 10)$.

**Proof.** Let $x$ be a fixed central involution of $G = G_2(4):2$, i.e., a point of $O_1$. It is clear from the suborbit diagram that every other involution is at distance at most 4 from $x$. Therefore the point-line geometry is connected and has diameter 4. Now let $L$ be any line, then from the suborbit diagram there exists an $i \in \{0, 1, 2, 3\}$ such that $L$ intersects $O_i$ in one point and $O_{i+1}$ in two points. Therefore there exists a unique point on $L$ nearest to $x$. Since the automorphism group acts transitively on points, $O_1$ is a near octagon. Since there are exactly $2 + 20 = 22$ points collinear with $x$ (the elements of $O_{1a} \cup O_{1b}$), this near octagon has order $(2, 10)$.

---

Figure 5.1: The suborbit diagram for the central involutions of $G_2(4):2$

---

4 orbitals is synonymous with suborbits
5.2.2. The $L_3(4)$ Near Octagon

If instead of the group $G_2(4):2$, we start with $G = L_3(4):2$ and take the conjugacy class $2A$ of 315 central involutions of $G$, then the same construction as before by fixing an element $\omega$ in this conjugacy class gives us the suborbit diagram of Figure 5.2. The suborbit description for this case is given in Table 5.2. By a similar argument as before we see that this geometry is a near octagon of order $(2, 4)$, thus proving Theorem 5.1.2(1).

We also note that the central involutions distinct from $\omega$ which commute with $\omega$ are those of the set $O_{1a} \cup O_{1b} \cup O_{2a}$. To gain a better understanding of this $L_3(4)$ near octagon, and to determine its automorphism group, we now describe some of its properties using the projective plane $PG(2, 4)$.

Table 5.2.: Suborbit description for $L_3(4):2$

Let $V$ be a 3-dimensional vector space over the field $F_4$ with basis $(\bar{e}_1, \bar{e}_2, \bar{e}_3)$, and denote by $(\bar{f}_1, \bar{f}_2, \bar{f}_3)$ the dual basis in the dual space $V'$ obtained by taking the functional $\bar{f}_i$’s satisfying the property that $\bar{f}_i(\bar{e}_j) = \delta_{ij}$ for $i, j \in \{1, 2, 3\}$. We get a projective space $PG(V) \cong PG(2, 4)$ from this vector space $V$ by taking the 1-dimensional subspaces of $V$ as points $P$, and the 2-dimensional subspaces as lines $L$; incidence is containment. For a 1-dimensional subspace $\langle f \rangle$ of $V'$, we get a 2-dimensional subspace of $V$ given by $\{u \in V \mid f(u) = 0\}$, implying that we can identify each line of $PG(V)$ with a point of $PG(V')$. A collineation of $PG(V) = (P, L, I)$ is a bijective map $\theta : P \cup L \to P \cup L$ such that $\theta(P) = P$, $\theta(L) = L$ and $(p, L) \in I$ iff $(\theta(p), \theta(L)) \in I$ (incidence preserving). A correlation is a bijective incidence preserving map which switches the sets $P$ and $L$.

It is well-known that the group of all collineations of $PG(V)$ is equal to the group $PGL(V)$. Thus with each collineation $\theta$ of $PG(V)$, there is associated a nonsingular $3 \times 3$ matrix $A$ over $F_4$ and an automorphism $\tau$ of $F_4$ such that the point $\langle x_1\bar{e}_1 + x_2\bar{e}_2 + x_3\bar{e}_3 \rangle$ of $PG(V)$...
is mapped to the point \(\langle x'_1 \bar{e}_1 + x'_2 \bar{e}_2 + x'_3 \bar{e}_3 \rangle\) of PG(V), where \([x'_1 \ x'_2 \ x'_3]^T = A \cdot [x_1 \ x_2 \ x_3]^T\). While the automorphism \(\tau\) of \(\mathbb{F}_4\) is uniquely determined by \(\theta\), the matrix \(A\) itself is only determined up to a nonzero scalar factor. However, all matrices \(A\) corresponding to \(\theta\) have the same determinant as \(k^3 = 1\) for every \(k \in \mathbb{F}_4 \setminus \{0\}\). The element \(\theta\) of \(\text{PTL}(V)\) also permutes the lines of PG(V). Specifically, if the “line” \(\langle y_1 f_1 + y_2 f_2 + y_3 f_3 \rangle\) is mapped to the “line” \(\langle y'_1 f_1 + y'_2 f_2 + y'_3 f_3 \rangle\), then \([y'_1 \ y'_2 \ y'_3]^T = (A^T)^{-1} \cdot [y_1 \ y_2 \ y_3]^T\).

With each correlation \(\sigma\) of PG(V), there is also associated a nonsingular 3×3 matrix \(A\) over \(\mathbb{F}_4\) and an automorphism \(\tau\) of \(\mathbb{F}_4\) such that the point \(\langle x_1 \bar{e}_1 + x_2 \bar{e}_2 + x_3 \bar{e}_3 \rangle\) is mapped to the “line” \(\langle y_1 f_1 + y_2 f_2 + y_3 f_3 \rangle\), where \([y_1 \ y_2 \ y_3]^T = A \cdot [x_1 \ x_2 \ x_3]^T\). Again, the automorphism \(\tau\) of \(\mathbb{F}_4\) is uniquely determined by \(\theta\), but \(A\) is only determined up to a nonzero scalar factor. If \(A\) and \(\tau\) are as above, then \(\theta\) will map the “line” \(\langle y_1 f_1 + y_2 f_2 + y_3 f_3 \rangle\) to the point \(\langle x'_1 \bar{e}_1 + x'_2 \bar{e}_2 + x'_3 \bar{e}_3 \rangle\), where \([x'_1 \ x'_2 \ x'_3]^T = (A^T)^{-1} \cdot [x_1 \ x_2 \ x_3]^T\).

Let \(G_1 \cong \text{PSL}_3(4) = L_3(4)\) denote the group of all collineations of PG(V) for which the field automorphism \(\tau\) is the identity and the matrix \(A\) has determinant 1\(^5\). Let \(G_2\) denote the group of all collineations of PG(V) for which \(\det(A) = 1\) and let \(G\) denote the group of all collineations and correlations of PG(V) for which \(\det(A) = 1\). Then \(G_1\) has index 2 in \(G_2\) which itself has index 2 in \(G\). If \(G_3\) denotes the set of all elements of \(G\) for which \(A = I_3\), then \(G_3 \cong C_2 \times C_2\). Moreover, \(G\) is the internal semidirect product \(G_1 \rtimes G_3\). So, \(G\) is a group of type \(L_3(4):2^2\). Note also that \(G_1\) is the derived subgroup of \(G\), and that the group of all collineations and correlations of PG(V) has type \(L_3(4):D_{12}\).

The little projective group \(\text{PSL}_3(4) = L_3(4)\) is generated by the elations of PG(2,4), which are collineations that fix every point on a line \(L\), called the axis of the elation, and fix every line through a point \(p\) on \(L\), called the center of the elation. We denote the set of all elations of PG(V) by \(\Sigma\). If we treat the axis \(L\) as the line at infinity and \(p\) as the direction, then the elation \(\sigma \in \Sigma\) corresponds to a translation of the affine plane \(\text{AG}(2,4)\) that we get by “removing” the line \(L\). We note the following easily proved properties (where group elements are composed from left to right).

**Lemma 5.2.2.** (1) If \(\sigma \in \Sigma\) is an elation of PG(2,4) with center \(p\) and axis \(L\), and \(\theta\) is a collineation of PG(2,4), then \(\theta^{-1} \sigma \theta\) is an elation of PG(2,4) with center \(p^\theta\) and axis \(L^\theta\).

(2) If \(\sigma \in \Sigma\) is an elation of PG(2,4) with center \(p\) and axis \(L\), and \(\theta\) is a correlation of PG(2,4), then \(\theta^{-1} \sigma \theta\) is an elation of PG(2,4) with center \(L^\theta\) and axis \(p^\theta\).

Since the characteristic of the field is 2, we see that the (non-identity) elations \(\Sigma\) of PG(2,4) form a conjugacy class of involutions in the group generated by collineations and correlations of PG(2,4). The elations are all contained in the group \(L_3(4)\), and moreover their conjugacy class is precisely the involution class \(2A\) of the group \(L_3(4):2^2\) which has \(L_3(4)\) as its derived subgroup. Therefore, in our construction of the near octagon \(O_1\), we are taking the 315 elations of the projective plane PG(2,4) as points on which the group \(G = L_3(4):2^2\) acts via conjugation. In Section 5.5 we will show that the group \(G\) is in fact the full automorphism group of the near octagon \(O_2\).

We note that the group \(G\) has a natural action on the set \(\mathcal{F}\) of 105 flags of PG(2,4). This action is transitive and there are four suborbits (orbits with respect to the stabilizer

\(^5\)This is well-defined. There are different choices possible for \(A\), but the determinants are always the same.
of a fixed flag), implying that the group $G$ acts distance-transitively on the point set of the unique generalized hexagon $H(4,1)$ of order $(4,1)$. Recall that this is the generalized hexagon whose points are the elements of $\mathcal{F}$ and whose lines are the points and lines of $\text{PG}(2,4)$, with incidence being reverse containment. The fact that $G$ acts distance-transitively implies that $G$ must also act primitively on the set of 105 points of $\text{GH}(4,1)$ (a property that holds for all generalized polygons). Consulting GAP’s library of primitive permutation groups \cite{gap}, we see that there exists a unique primitive permutation group on 105 letters that is of the type $L_{3}(4):2^2$. To verify our claims and to construct the suborbit diagram in Figure 5.2 we have used this implementation of the group in GAP.

We now give a computer aided proof of the fact the near octagon $O_2$ is a full subgeometry of the near octagon $O_1$.

**Theorem 5.2.3.** There exists a full embedding of $O_2$ into $O_1$ mapping lines of the line spread $S_2$ to lines of the line spread $S_1$. Two embedded points are collinear in $O_1$ if and only if they are collinear in $O_2$.

**Proof.** By the Atlas \cite{atlas}, the group $G := G_2(4):2$ has a maximal subgroup $H$ of type $\text{SL}_3(4):2^2$. If we regard $G$ as naturally acting on the dual split Cayley hexagon $H(4)^D$, then $H$ is the stabilizer of a subhexagon of order $(4,1)$. And in fact this is the presentation of this group and its subgroup which we have used in GAP to verify the claims that follow. Let $Z := Z(H')$ be the center of the derived subgroup $H' \cong \text{SL}_3(4)$ of $H$. Then $Z \cong C_3$, $J := H/Z \cong \text{L}_3(4):2^2$ and $J' = H'/Z \cong \text{L}_3(4)$. For $x \in H \cong \text{L}_3(4):2^2$, we let $\overline{x}$ denote the element $xZ$ of $H/Z \cong \text{L}_3(4):2^2$.

There exists a bijective correspondence between the involutions of the group $H' \cong \text{L}_3(4)$ and the involutions of the group $J' = H'/Z \cong \text{L}_3(4)$. If $\sigma$ is an involution of $H'$, then $\sigma \notin Z \cong C_3$ and so $\overline{\sigma}$ is an involution of $J' = H'/Z$. Conversely, if $\tau Z$ is an involution of $J' = H'/Z$, then there exists a unique involution $\sigma$ of $H'$ for which $\overline{\sigma} = \tau Z$. Now let $\Sigma$ denote the set of all involutions of $H'$ for which $\overline{\sigma}$ is an involution of central involutions of $J'$. Then $\Sigma$ is a conjugacy class of involutions in both $H'$ and $H$. Indeed, if $\sigma \in \Sigma$ and $x \in H$, then $x^{-1}\sigma x = \overline{x^{-1}\sigma x} \in \overline{\Sigma}$ as $\overline{x} \in H/Z$ and $\overline{\sigma} \in \overline{\Sigma}$, and therefore the involution $x^{-1}\sigma x$ also belongs to $\Sigma$.

As $\Sigma$ is a conjugacy class of involutions in $H$, it is contained in a conjugacy class of involutions of $G = G_3(4):2^2$. We have verified with GAP that all elements of $\Sigma$ are in fact central involutions of $G$. Since $x^{-1}\sigma x = \overline{x^{-1}\sigma x}$ for all $\sigma \in \Sigma$ and all $x \in H$, the action of $H \cong \text{SL}_3(4):2^2$ on the set $\Sigma$ gives rise to the same suborbit diagram as the action of $H/Z \cong \text{L}_3(4):2^2$ on $\overline{\Sigma}$ (depicted in Figure 5.2). We suppose that $O_2$ is the near octagon of order $(2,4)$ defined on the involutions of the set $\Sigma$, where two distinct involutions $\sigma_1$ and $\sigma_2$ of $\Sigma$ are collinear whenever the suborbit with respect to $\sigma_1$ which contains $\sigma_2$ has size 2 or 8. We suppose that $O_1$ is the near octagon of order $(2,10)$ defined on the central involutions of $G = G_2(4):2$. Since all elements of $\Sigma$ are central involutions of $G_2(4):2$, we have identified each point of $O_2$ with a point of $O_1$.

Now, fix an involutions $\omega \in \Sigma$. We denote by $O_0, O_{1a}, O_{1b}, O_{2a}, O_{2b}, O_{3a}, O_{3b}$ and $O_4$ the suborbits with respect to $\omega$ under the action of $H$ using the same notation as before. We also know that the action of the stabilizer of $G_2(4):2$ with respect to $\omega$ on its central involutions gives similar suborbits, which we denote by $O'_{1a}, O'_{1b}, O'_{2a}, O'_{2b}, O'_{3a}, O'_{3b}$ and $O'_4$. With the help of GAP, we have also checked that each of the suborbit $O$ of $\Sigma$ is contained in $O'$. We know that the suborbits $O_{1a}$ and $O_{1b}$ contain those points of $O_2$ that
are at distance 1 from ω in O₂. We also know that the suborbits O′₁a and O₁b contain those points of O₁ that are distance 1 from ω in O₁. So, if x and y are two points in O₂, then we have shown that x and y are collinear in O₂ if and only if they are collinear in O₁. Every line of O₂, which is a collection of three mutually collinear points, is thus a line of O₁.

The unique line of S₂ through ω is {ω}∪O₁a, which must be equal to {ω}∪O′₁a (O₁a = O′₁a since they have the same cardinality). Therefore, every line of S₂ is a line of S₁.

5.3. A Family of Near Octagons

Suppose S = (P, L, I) is a finite near octagon of order (s, t), s ≥ 2, and S is a line spread of S. For every point x of S, let Lₓ denote the unique line of S containing x. We define a number of additional sets of points of S.

- For every point x of S, we define Γ′₁(x) := Lₓ \ {x} and Γ₁(x) := Γ₁(x) \ Γ′₁(x).
- For every point x of S and every i ∈ {2, 3}, we define Γᵢ(x) to be the set of points of Γᵢ(x) that are collinear with a point of Γᵢ₋₁(x), and we put Γᵢ(x) := Γᵢ(x) \ Γᵢ₋₁(x).

Throughout this section, we assume that there exists a positive divisor t′ of t, with t′ ≠ t such that the following hold for every point x of S:

(P1) Every point of Γ₂(x) is incident with t′ lines meeting Γᵢ(x).
(P2) Every point of Γₙ(x) is incident with a unique line meeting Γ₁(x).
(P3) Every point of Γ₃(x) is incident with t′ lines meeting Γₙ(x).
(P4) Every point of Γₙ(x) is incident with t lines meeting Γ₂(x).

From the suborbit diagrams of O₁ and O₂ (see Figures 5.1, 5.2), described in the previous section, we can see that both of these near octagons satisfies these four properties. For O₁, we have s = 2, t = 10 and t′ = 2, while for O₂ we have s = 2, t = 4 and t′ = 2. When t′ = 1, it can be shown that any near polygon S satisfying these properties must be the direct product of a generalized hexagon of order (s, t − 1) with a line of size s + 1. We call this the trivial example. Therefore, all the results we prove in this section for the near octagon S are true for both O₁ and O₂ (and for the trivial example). It will also be clear from our discussion that for any point x, the sets Γ₀(x), Γ₁(x), Γₙ(x), Γ₂(x), Γₙ(x), Γ₃(x), Γ₄(x) and Γ₅(x) correspond to the suborbits O₀(x), O₁a(x), O₁b(x), O₂a(x), O₂b(x), O₃a(x), O₃b(x) and O₄(x), respectively.

In the lemmas below, x denotes some fixed point of S. A point y of S is said to be of type i ∈ {0, 1, 2, 3, 4} if y ∈ Γₖ(x). A point y of S is said to be of type i′ or i″, for i ∈ {1, 2, 3}, if it belongs to Γ′ₖ(x) or Γₖ(x), respectively. A line L of S is said to have type (i, j) for i, j ∈ {0, 1′, 1″, 2′, 2″, 3′, 3″, 4} if it contains a unique point of type i and s points of type j; for example, the line Lₓ is of type (0, 1′). We will ultimately show that, just like the case of near octagons O₁ and O₂, every line of S has type (0, 1′), (0, 1″), (1′, 2′), (1′, 2″), (1″, 2′), (2′, 3′), (2″, 3′), (2″, 3″), (3′, 4) or (3″, 4), while every line of the line spread S has type (0, 1′), (1′, 2′), (2′, 3′) or (3′, 4).

Γ₂(x) and Γ₃(x) are assumed to be nonempty
Lemma 5.3.1. The point $x$ is contained in a unique line of type $(0,1')$ and $t$ lines of type $(0,1'')$. We have $|\Gamma_0(x)| = 1$, $|\Gamma_1(x)| = s$ and $|\Gamma_1''(x)| = st$. There is a unique line of type $(0,1')$, namely $L_x$, and every line of $S$ meeting $\Gamma_0(x) \cup \Gamma_1'(x)$ coincides with $L_x$.

Proof. Follows directly from the definitions.

Lemma 5.3.2. Every point $y \in \Gamma_2'(x)$ is contained in a (necessarily unique) quad together with $x$. This quad has order $(s,t)$.

Proof. By definition of the set $\Gamma_2'(x)$, the line $L_x = \{x\} \cup \Gamma_1'(x)$ contains a (necessarily unique) point collinear with $y$. By Property (P1), there are precisely $t' \geq 1$ points in $\Gamma_1'(x)$ collinear with $y$. As the points $x$ and $y$ have $t' + 1 \geq 2$ common neighbors (and $s \geq 2$), they are contained in a unique quad, necessarily of order $(s,t')$, by Theorem 1.3.8.

Lemma 5.3.3. No point of $\Gamma_2''(x)$ can be contained in a quad together with $x$.

Proof. Let $y \in \Gamma_2''(x)$. By Property (P2), there is a unique line through $y$ meeting $\Gamma_1'(x)$, and by definition of the set $\Gamma_2''(x)$, there are no lines through $y$ meeting $\Gamma_1'(x)$. Hence, $x$ and $y$ have a unique common neighbor, implying that they cannot be contained in a quad.

Lemma 5.3.4. Every quad through a point $y$ of $S$ contains the line $L_y$.

Proof. Without loss of generality, we can take $y = x$. Suppose $Q$ is a quad through $x$ not containing the line $L_x$. Then no $y \in \Gamma_2(x) \cap Q$ is collinear with a point of $L_x$, as otherwise $L_x$ will be contained in $Q$. This implies that $\Gamma_2(x) \cap Q \subseteq \Gamma_2''(x)$, which contradicts Lemma 5.3.3.

Lemma 5.3.5. For every quad $Q$ of $S$, the lines of the spread $S$ that are contained in $Q$ form a line spread of $Q$.

Proof. If this were not the case, then there would exist a line of $S$ meeting $Q$ in a single point $y$ which would contradict Lemma 5.3.4.

Lemma 5.3.6. Through every point $y \in \Gamma_1'(x)$, there is a unique line of type $(0,1')$ and $t$ lines of type $(1',2')$.

Proof. This follows from the definition of the set $\Gamma_2'(x)$: every line through $y$ which is not equal to the unique line of type $(0,1')$ (the line $L_x$) must be of type $(1',2')$.

Lemma 5.3.7. We have $|\Gamma_2'(x)| = s^2t$.

Proof. By Lemmas 5.3.1 and 5.3.6, the number of edges between $\Gamma_1'(x)$ and $\Gamma_2'(x)$ in the collinearity graph is equal to $|\Gamma_1'(x)| \cdot t \cdot s = s^2t$. As any point of $\Gamma_2'(x)$ is collinear with a unique point of $L_x$, from double counting these edges we see that $|\Gamma_2'(x)| = s^2t$.

Lemma 5.3.8. There are precisely $\frac{1}{t}$ quads through any given point of $S$.

Proof. Without loss of generality, we prove this for the point $x$. Every quad through $x$ has order $(s,t')$ and contains $s^2t'$ points at distance 2 from $x$. All these $s^2t'$ points belong to $\Gamma_2'(x)$ by Lemma 5.3.3. From Lemmas 5.3.2 and 5.3.7 it then follows that there are precisely $\frac{|\Gamma_2'(x)|}{s^2t'} = \frac{s^2}{s^2t'} = \frac{1}{t}$ quads through $x$.

Lemma 5.3.9. Every line $M$ through a point $y$ of $S$ distinct from $L_y$ is contained in a unique quad.
Proof. Without loss of generality, we may suppose that \( y = x \). As any quad through \( x \) contains the line \( L_x \) by Lemma [5.3.4][1.3.10], there is at most one quad through \( M \) (see Lemma [5.3.10]). Since every quad through \( x \) has order \( (s, t') \), the \( \frac{1}{t} \) quads through \( x \) cover \( t' \cdot \frac{1}{t} = t \) lines through \( x \) distinct from \( L_x \). As these are all lines through \( x \) distinct from \( L_x \), \( M \) must be contained in a unique quad.

Lemma 5.3.10. For every \( y \in \Gamma'_1(x) \), the line \( L_y \) has type \((1', 2')\). For every \( z \in \Gamma'_2(x) \), the line \( L_z \) has type \((1'', 2')\).

Proof. By Lemma 5.3.9 the line \( xy \) is contained in a unique quad \( Q \). By Lemma 5.3.3 \( L_x \) and \( L_y \) are two disjoint lines contained in \( Q \), and so every point of \( L_y \setminus \{y\} \) belongs to \( \Gamma'_2(x) \), as it is collinear with a point of \( L_x \setminus \{x\} \). Therefore, \( L_y \) has type \((1'', 2')\). The \( st \) mutually distinct lines \( L_y \) with \( y \in \Gamma'_1(x) \) cover \( s^2t \) points of \( \Gamma'_2(x) \). By Lemma 5.3.7 these are all the points of \( \Gamma'_2(x) \). So, for every \( z \in \Gamma'_2(x) \), the line \( L_z \) has type \((1'', 2')\).

Lemma 5.3.11. Let \( y \in \Gamma'_1(x) \). Then \( y \) is contained in a unique line of type \((0, 1'')\), \( t' \) lines of type \((1'', 2')\) and \( t - t' \) lines of type \((1'', 2'')\).

Proof. There is a unique line through \( y \) containing \( x \), namely the line \( xy \). This line contains precisely \( s \) points of \( \Gamma'_1(x) \). There is no line through \( y \) meeting \( \Gamma'_1(x) \) since otherwise \( x \) would be collinear with two distinct points of that line, contradicting the fact that \( S \) is a near polygon. So, every line through \( y \) which is distinct from \( xy \) meets \( \Gamma'_2(x) \), and necessarily contains precisely \( s \) points of \( \Gamma'_2(x) \).

By Lemma 5.3.9 there is a unique quad \( Q \) (of order \( (s, t') \)) through the line \( xy \). By Lemma 5.3.3 the \( t' \) lines of \( Q \) through \( y \) which are distinct from \( xy \) all contain precisely \( s \) points of \( \Gamma'_2(x) \). Conversely, suppose that \( L \) is a line through \( y \) containing a point \( u \in \Gamma'_2(x) \). The unique quad through \( x \) and \( u \) is a convex subspace and therefore the lines \( L = yu \) and \( xy \) are contained in this quad, implying that the quad coincides with \( Q \). So, \( L \) is one of the \( t' \) lines of \( Q \) through \( y \) distinct from \( xy \). The remaining \( t - t' \) lines through \( y \) must be of type \((1'', 2'')\).

Lemma 5.3.12. We have \( |\Gamma'_2(x)| = s^2t(t - t') \).

Proof. By Lemmas 5.3.1 and 5.3.11 the number of edges between \( \Gamma'_1(x) \) and \( \Gamma'_2(x) \) is equal to \( |\Gamma'_1(x)| \cdot (t - t')s = s^2t(t - t') \). By Property (P2), we know that the number of edges is also equal to \( |\Gamma'_2(x)| \).

Lemma 5.3.13. Let \( y \in \Gamma'_2(x) \). Then \( y \) is incident with a unique line of type \((1', 2')\), \( t' \) lines of type \((1'', 2')\) and \( t - t' \) lines of type \((2', 3')\).

Proof. The lines through \( y \) meeting \( \Gamma'_1(x) \) (necessarily in a unique point) are precisely the \( t' + 1 \) lines through \( y \) that are contained in the unique quad \( Q \) through \( x \) and \( y \). By Lemma 5.3.3, each of these lines contains precisely \( s \) points of \( \Gamma'_2(x) \), and hence they have type \((1'', 2')\) or \((1', 2')\). Note that there is a unique line through \( y \) meeting \( L_x = \{x\} \cup \Gamma'_1(x) \), which is the unique line of type \((1', 2')\) through \( y \). By the definition of the set \( \Gamma'_2(x) \), the remaining \( t - t' \) lines through \( y \) all contain \( s \) points of \( \Gamma'_3(x) \), and thus have type \((2', 3')\).

Lemma 5.3.14. Through every point \( y \in \Gamma'_2(x) \), there is a unique line meeting \( \Gamma'_2(x) \).

Proof. By definition of the set \( \Gamma'_2(x) \), we know that there is at least one such line. Suppose two lines through \( y \) meet \( \Gamma'_2(x) \) in the points \( u_1 \) and \( u_2 \), respectively. By Lemma 5.3.13, \( u_i \) with \( i \in \{1, 2\} \) is collinear with a unique point \( v_i \in L_x \). This point necessarily coincides with the unique point \( v \) of \( L_x \) at distance \( 2 \) from \( y \) (the near polygon property).
Hence, \( v = v_1 = v_2 \). Since the points \( y \) and \( v \) have two distinct neighbors, namely \( u_1 \) and \( u_2 \), they are contained in a unique quad \( Q \). The line \( L_x \) meets this quad \( Q \) in a unique point (namely \( v \)), but this contradicts Lemma 5.3.5.

**Lemma 5.3.15.** We have \( |\Gamma_3'(x)| = s^3(t-t') \).

*Proof.* By Lemmas 5.3.7 and 5.3.13 the number of edges between \( \Gamma_2'(x) \) and \( \Gamma_3'(x) \) is equal to \( |\Gamma_2'(x)| \cdot (t-t')s = s^3(t-t') \). By Lemma 5.3.14, the number of these edges is also equal to \( |\Gamma_3'(x)| \). \qed

**Lemma 5.3.16.** For every \( y \in \Gamma_2''(x) \), the line \( L_y \) has type \((2'',3')\). For every \( y \in \Gamma_3'(x) \), the line \( L_y \) has type \((2',3')\).

*Proof.* Let \( y \in \Gamma_2''(x) \). By Property (P2), there exists a unique point \( z \in \Gamma_1'(x) \) collinear with \( y \). By Lemma 5.3.10, the line \( L_z \) has type \((1'',2')\) and so it is distinct from \( yz \). By Lemmas 5.3.4 and 5.3.9, there is a unique quad \( Q \) through \( L_z \) and \( yz \). By Lemma 5.3.3 this quad cannot contain \( x \). So, \( x \) lies at distance 1 from \( Q \) and is classical with respect to \( Q \), implying that \( L_y \setminus \{y\} \subseteq \Gamma_3(x) \). By Lemma 5.3.5, the line \( L_y \) is contained in \( Q \) and so the line \( L_y \) is parallel at distance 1 from \( L_z \) (see Lemma 1.3.7). Hence, every point of \( L_y \setminus \{y\} \) is collinear with a point of \( L_z \setminus \{z\} \subseteq \Gamma_2'(x) \), implying that \( L_y \setminus \{y\} \subseteq \Gamma_3(x) \).

The \( s^3(t-t') \) mutually disjoint lines \( L_z \) with \( z \in \Gamma_2''(x) \) cover \( s^3(t-t') \) points of \( \Gamma_3'(x) \). By Lemma 5.3.15, these are all the points of \( \Gamma_3'(x) \). So \( y \in \Gamma_3'(x) \) and hence the line \( L_y \) has type \((2',3')\). \qed

**Lemma 5.3.17.** For any \( y \in \Gamma_3''(x) \cup \Gamma_4(x) \), the line \( L_y \) has type \((3'',4)\).

*Proof.* This follows from Lemmas 5.3.1, 5.3.10, 5.3.14 and the fact that \( S \) is a line spread of \( S \). \qed

**Lemma 5.3.18.** There are no lines meeting \( \Gamma_3'(x) \) and \( \Gamma_3''(x) \).

*Proof.* Suppose \( L \) is a line containing points \( u' \in \Gamma_3'(x) \) and \( u'' \in \Gamma_3''(x) \), and let \( y \) denote the unique point of \( \Gamma_2(x) \) on \( L \). By the definition of \( \Gamma_3''(x) \), we must have \( y \in \Gamma_2''(x) \) since no point of \( \Gamma_3''(x) \) is collinear with a point of \( \Gamma_2(x) \). By Lemma 5.3.14, the point \( u' \) is collinear with a unique point \( v \in \Gamma_3'(x) \). By Lemma 5.3.10, the line \( L_v \) meets \( \Gamma_3'(x) \) and so is distinct from \( vu' \). By Lemmas 5.3.4 and 5.3.9, there exists a unique quad \( Q \) through \( L_v \) and \( vu' \). This quad also contains a point of \( \Gamma_3''(x) \), and so the \( t' \) lines of \( Q \) through \( u' \) distinct from \( vu' \) all meet \( \Gamma_3(x) \). By Property (P3), we know that these \( t' \) lines meet \( \Gamma_2(x) \). By Property (P3), we know that these are all the lines through \( u' \) meeting \( \Gamma_2'(x) \). So, the line \( L \) is contained in \( Q \). But then every point of \( L \setminus \{y\} \) is collinear with a point of \( L_v \setminus \Gamma_1'(x) \subseteq \Gamma_2'(x) \), implying that each point of \( L \setminus \{y\} \) belongs to \( \Gamma_3'(x) \). This contradicts the fact that \( u'' \in \Gamma_3'(x) \).

The following is a consequence of Lemmas 5.3.1, 5.3.6, 5.3.10, 5.3.11, 5.3.13, 5.3.14, 5.3.16, 5.3.17, and 5.3.18.

**Corollary 5.3.19.**

- Every line of \( S \) has type \((0,1'), (0,1''), (1',2'), (1'',2'), (1'',2''), (2',3'), (2'',3'), (2'',3''), (3',4) \) or \((3'',4)\).

- Every line of the spread \( S \) has type \((0,1'), (1'',2'), (2',3') \) or \((3'',4)\).

We can now draw a diagram for \( S \) which looks similar to Figures 5.1 and 5.2. This is done in Figure 5.3, though we still need to prove some of the information that is contained in the diagram.
Lemma 5.3.20. Let \( y \in \Gamma''_2(x) \) and let \( z \) be the unique point of \( \Gamma''_1(x) \) collinear with \( y \). Then there exists a quad \( Q \) through \( y \) and \( z \) such that the \( t' \) lines of \( Q \) through \( y \) distinct from \( yz \) have type \((2',3')\).

Proof. By Property (P2), there is a unique point \( z \in \Gamma''_1(x) \) collinear with \( y \). By Lemma 5.3.10, the line \( L_z \) contains \( s \) points of \( \Gamma'_2(x) \). Consider now the unique quad \( Q \) through \( L_z \) and \( yz \). If \( L \) is one of the \( t' \) lines of \( Q \) through \( y \) distinct from \( yz \), then every point of \( L \setminus \{y\} \) is collinear with a point of \( L_z \setminus \{z\} \subseteq \Gamma'_2(x) \) and hence is contained in \( \Gamma''_2(x) \). \( \square \)

Lemma 5.3.21. Every point \( y \) of \( \Gamma''_3(x) \) is incident with a unique line of type \((2',3')\), \( t' \) lines of type \((2'',3')\) and \( t - t' \) lines of type \((3',4)\).

Proof. By Lemma 5.3.14, there is a unique line of type \((2',3')\) through \( y \) and by Property (P3), there are precisely \( t' \) lines of type \((2',3')\) through \( y \). The remaining \( t - t' \) lines through \( y \) should all have type \((3',4)\). \( \square \)

Lemma 5.3.22. Every point \( y \) of \( \Gamma''_3(x) \) is incident with a unique line of type \((1'',2'')\), \( t' \) lines of type \((2'',3')\) and \( t - t' \) lines of type \((2'',3'')\).

Proof. By Lemmas 5.3.12 and 5.3.20, the number of edges between \( \Gamma''_2(x) \) and \( \Gamma''_3(x) \) is at least \( |\Gamma''_2(x)| \cdot s t' = s^3 t' (t - t') \), with equality if and only if every point of type \( 2'' \) is incident with precisely \( t' \) lines of type \((2'',3')\). By Lemma 5.3.15 and Property (P3), we know that the number of edges between \( \Gamma''_2(x) \) and \( \Gamma''_3(x) \) is precisely \( |\Gamma''_3(x)| \cdot t' = s^3 t' (t - t') \). So, the point \( y \in \Gamma''_3(x) \) is incident with precisely \( t' \) lines of type \((2'',3')\). By Property (P2), \( y \) is incident with a unique line of type \((1'',2'')\). The remaining \( t - t' \) lines through \( y \) should have type \((2'',3'')\). \( \square \)

Lemma 5.3.23. Every point \( y \) of \( \Gamma''_4(x) \) is contained in \( \frac{1}{f} \) lines of type \((2'',3'')\) and \( t + 1 - \frac{1}{f} \) lines of type \((3'',4)\).

Proof. This follows from Property (P4)\footnote{This is the first time we have used (P4).} and the discussion so far regarding the types of lines in \( S \), where we deduced that the only types of lines through a point of type \( 3'' \) are \((2'',3'')\) and \((3'',4)\). \( \square \)

Lemma 5.3.24. We have \( |\Gamma''_3(x)| = s^3 t' (t - t')^2 \).

Proof. By Lemmas 5.3.12 and 5.3.22, the number of edges between \( \Gamma''_2(x) \) and \( \Gamma''_3(x) \) is equal to \( |\Gamma''_2(x)| \cdot (t - t')s = s^3 t (t - t')^2 \). By Lemma 5.3.23 this number is also equal to \( |\Gamma''_3(x)| \cdot \frac{1}{f} \). Hence, \( |\Gamma''_3(x)| = s^3 t' (t - t')^2 \). \( \square \)

Lemma 5.3.25. Let \( L \) be a line of \( S \) meeting \( \Gamma''_3(x) \) and \( \Gamma_4(x) \). If \( Q \) is a quad through \( L \), then \( Q \) contains at most one point at distance 2 from \( x \).

Proof. Since the quad \( Q \) contains a point at distance 4 from \( x \), it contains a point at distance 2 from \( x \) if and only if \( x \) is classical with respect to \( Q \). But then \( d(x,Q) = 2 \) and so \( Q \) contains a unique point at distance 2 from \( x \). \( \square \)

Lemma 5.3.26. Let \( L \) be a line of the spread \( S \) having type \((3'',4)\). Then all \( \frac{t}{f} \) quads through \( L \) contain a unique point of type \( 2'' \) and a unique line of type \((2'',3')\). This point of type \( 2'' \) is the unique point of the quad at distance 2 from \( x \), and this line of type \((2'',3')\) belongs to \( S \).
Conversely, by Lemma 5.3.26, any of the \( \Gamma''_3(x) \) containing a unique point of \( \Gamma''_3(x) \) by Lemma 5.3.25. These are all the quads through \( L \). Let \( Q \) be any of these \( \frac{t}{t'} \) quads and let \( z \) denote the unique point in \( Q \cap \Gamma_2(x) \). By Lemmas 5.3.20 and 5.3.22, the \( t' \) lines of type \((2'',3')\) through \( z \) are all contained in a quad \( Q' \) through \( z \). As \( Q' \) contains a point of \( \Gamma''_3(x) \), we have \( Q \neq Q' \) and so \( Q \cap Q' \) is at most a line. As \( L_z \subseteq Q \cap Q' \), we have \( L_z = Q \cap Q' \). Clearly, \( L_z = Q \cap Q' \) is the unique line of type \((2'',3')\) of \( Q \).

\[ \square \]

**Lemma 5.3.27.** Every point \( y \) of \( \Gamma_4(x) \) is incident with \( \frac{t}{t'} \) lines of type \((3',4)\) and \( t+1-\frac{t}{t'} \) lines of type \((3',4)\).

**Proof.** If \( L \) is a line through \( y \) meeting \( \Gamma_3(x) \), then Lemmas 5.3.4, 5.3.9, and 5.3.17 imply that there is a unique quad through \( L \) and this quad contains the line \( L_y \) of type \((3',4)\). Conversely, by Lemma 5.3.26, any of the \( \frac{t}{t'} \) quads through \( L_y \) contains a unique line through \( y \) meeting \( \Gamma_3(x) \). So, there are \( \frac{t}{t'} \) lines through \( y \) meeting \( \Gamma''_3(x) \) and \( t+1-\frac{t}{t'} \) lines meeting \( \Gamma''_3(x) \).

\[ \square \]

**Lemma 5.3.28.** We have \(|\Gamma_4(x)| = s^4t'(t-t')^2\).

**Proof.** By Lemmas 5.3.15 and 5.3.21, the number of edges between \( \Gamma_4(x) \) and \( \Gamma_4(x) \) is equal to \(|\Gamma_3(x)| \cdot (t-t')s = s^4t(t-t')^2\). By Lemma 5.3.27, the number of such edges is also equal to \(|\Gamma_4(x)| \cdot \frac{t}{t'}\). It follows that \(|\Gamma_4(x)| = s^4t'(t-t')^2\).

\[ \square \]

We now have a full description of \( S \) in Figure 5.3 where we follow a similar convention as in Figures 5.1 and 5.2. Note that we have \(|\Gamma_0(x)| = 1, |\Gamma'(x)| = s, |\Gamma''_1(x)| = st, |\Gamma''_2(x)| = s^2t, |\Gamma''_3(x)| = s^3t(t-t')|, |\Gamma''_4(x)| = s^3t'(t-t')^2, and \(|\Gamma_4(x)| = s^4t'(t-t')^2\). Therefore, the total number of points in \( S \) can also be given in terms of the parameters \( s, t, t' \).

**Lemma 5.3.29.** Every point-quad pair in \( S \) is classical.

**Proof.** Without loss of generality, we may suppose that \( x \) is the point and \( Q \) is a quad of \( S \). If \( d(x,Q) = 1 \), then by Lemma 1.3.11 the pair \((x,Q)\) is classical. By Lemma 5.3.26, \((x,Q)\) is classical if \( Q \) contains points at distance 4 from \( x \). So, suppose \( Q \subseteq \Gamma_2(x) \cup \Gamma_3(x) \). Note that \( Q \cap \Gamma_2(x) \) must be nonempty. Let \( y \in Q \cap \Gamma_2(x) \). Then \( L_y \subseteq Q \) implies by
Lemma 5.3.10 that \( y \not\in \Gamma_2'(x) \). So, \( y \in \Gamma_2''(x) \). The line \( L_y \) meets \( \Gamma_3'(x) \). By Property (P2), \( y \) is collinear with a unique point \( z \) of \( \Gamma_3''(x) \). Denote by \( Q' \) the unique quad through \( yz \) and \( L_y \). By Lemmas 5.3.3 and 5.3.9, \( Q' \) is the unique quad through \( y \) meeting \( \Gamma_3''(x) \). By Lemmas 5.3.20 and 5.3.22, the \( t' \) lines of type \( (2'', 3') \) through \( y \) are the \( t' \) lines of \( Q' \) through \( y \) distinct from \( yz \). Each of the \( t - t' \) lines through \( y \) meeting \( \Gamma_3''(x) \) determines a quad together with \( L_y \) and such a quad has \( t' \) lines through \( y \) meeting \( \Gamma_3'(x) \). So, there are \( \frac{t - t'}{t'} = \frac{1}{t} - 1 \) quads through \( L_y \) meeting \( \Gamma_3'(x) \) and hence also \( \Gamma_4(x) \) as the unique line of \( S \) through a point of \( \Gamma_3''(x) \) meets \( \Gamma_4(x) \). We see that we have accounted for all \( \frac{t}{t'} \) quads through \( y \), and none of these quads can be equal to \( Q \), which is contained in \( \Gamma_2(x) \cup \Gamma_3(x) \).

**Lemma 5.3.30.** Two distinct lines \( L_1 \) and \( L_2 \) of the spread \( S \) lie at distance 1 from each other if and only if they are contained in the same quad. If \( d(L_1, L_2) = 1 \), then \( L_1 \) and \( L_2 \) are parallel.

**Proof.** If \( L_1 \) and \( L_2 \) are contained in a quad, then they are parallel and \( d(L_1, L_2) = 1 \). Conversely, suppose that \( d(L_1, L_2) = 1 \) and let \( x_1 \in L_1 \) and \( x_2 \in L_2 \) such that \( d(x_1, x_2) = 1 \). The unique quad through the line \( x_1x_2 \) then contains \( L_1 \) and \( L_2 \).

**Lemma 5.3.31.** Every two lines \( L \) and \( L' \) of \( S \) are parallel.

**Proof.** Let \( x \in L \) and \( x' \in L' \) such that \( d(L, L') = d(x, x') \). It suffices to show that every point of \( L \) has distance at most \( \delta := d(x, x') \) from \( L' \). Let \( x = y_0, y_1, \ldots, y_8 = x' \) be a path connecting \( x \) and \( x' \). Put \( L_i := L_{y_i}, i \in \{0, 1, \ldots, 8\} \). Then for every \( i \in \{1, 2, \ldots, \delta\} \), the lines \( L_{i-1} \) and \( L_i \) are either equal or parallel at distance 1. So, every point of \( L_{i-1} \) has distance at most 1 from a point of \( L_i \). This implies that every point of \( L = L_0 \) has distance at most \( \delta \) from \( L' = L_\delta \).

Let \( Q \) denote the set of quads of \( S \), and let \( S' \) be the point-line geometry with point set \( S \) and line set \( Q \), where incidence is containment.

**Lemma 5.3.32.** If \( L_1, L_2 \in S \), then the distance \( d \) between \( L_1 \) and \( L_2 \) in \( S' \) is equal to \( d(L_1, L_2) \).

**Proof.** Put \( d_1 := d \) and \( d_2 := d(L_1, L_2) \). Suppose \( L_1 = K_0, K_1, \ldots, K_{d_1} = L_2 \) is a (shortest) path in \( S' \) connecting \( L_1 \) and \( L_2 \). Then the \( K_i \)’s are mutually disjoint. Let \( x_0 \) be an arbitrary point of \( K_0 \) and for every \( i \in \{1, 2, \ldots, d_1\} \), let \( x_i \) denote the unique point of \( K_i \) collinear with \( x_{i-1} \). Then \( x_0 \in L_1 \) lies at distance at most \( d_1 \) from \( x_{d_1} \in L_2 \), showing that \( d_2 \leq d_1 \).

Suppose \( y_0, y_1, \ldots, y_{d_2} \) is a (shortest) path of length \( d_2 \) in \( S \) connecting a point \( y_0 \in L_1 \) with a point \( y_{d_2} \in L_2 \). In the sequence \( L_{y_0}, L_{y_1}, \ldots, L_{y_{d_2}} \), any two consecutive lines are either equal or at distance 1 from each other (in \( S' \)) by Lemma 5.3.30. So, we should also have that \( d_1 \leq d_2 \). We conclude that \( d_1 = d_2 \).

**Lemma 5.3.33.** \( S' \) has order \( (st', \frac{t}{t'} - 1) \).

**Proof.** By Lemma 5.3.5, every line of \( S' \) contains precisely \( 1 + st' \) points (this the size of a line spread of a generalized quadrangle of order \( (s, t') \)). By Lemmas 5.3.4 and 5.3.8, every line of \( S \) is contained in precisely \( \frac{t}{t'} \) quads, showing that every point of \( S' \) is incident with precisely \( \frac{t}{t'} \) lines of \( S' \).

**Lemma 5.3.34.** \( S' \) is a near hexagon.
Proof. Let \( L \in S \) and \( Q \in Q \). Denote by \( S_Q \) the set of lines of \( S \) contained in \( Q \). By Lemma 5.3.3, \( S_Q \) is a line spread of the generalized quadrangle \( Q \). Let \( x \) be an arbitrary point of \( L \). As \( x \) is classical with respect to the quad \( Q \), there exists a unique point \( x' \in Q \) nearest to \( x \). By Lemma 5.3.32, \( L_{x'} \) is the unique line of \( S_Q \) at distance \( d(x, x') \) from \( L_x = L \) in the geometry \( S' \). Every other line of \( S_Q \) has distance \( d(x, x') + 1 \) from \( L_x = L \).

It remains to show that \( S' \) has diameter 3. By Lemma 5.3.32, the diameter of \( S' \) is at most 3. If \( x_1 \) and \( x_2 \) are two points of \( S \) at distance 4 from each other, then the fact that \( L_{x_1} \) and \( L_{x_2} \) are parallel implies that they lie at distance 3 from each other (both in \( S \) as \( S' \)). So, the diameter of \( S' \) is indeed 3. \( \square \)

**Lemma 5.3.35.** Every two points of \( S' \) at distance 2 from each other have a unique common neighbor.

Proof. Let \( L_1, L_2 \in S \) be at distance 2 from each other in the geometry \( S' \) and suppose \( M_1, M_2 \in S \) are two distinct neighbors of \( L_1, L_2 \). The lines \( L_1, L_2, M_1, M_2 \) are mutually parallel by Lemma 5.3.31. By Lemma 5.3.32, there exist points \( x_1 \in L_1 \) and \( x_2 \in L_2 \) at distance 2 from each other. Also, by Lemma 5.3.32, the points \( x_1, x_2 \) have at least two common neighbors, one on \( M_1 \) and another one on \( M_2 \). So, \( x_1 \) and \( x_2 \) are contained in a quad \( Q \). This quad should contain the line \( L_{x_1} = L_1 \), but that is impossible since \( d(x_2, L_1) = 2 \). \( \square \)

The following is an immediate consequence of Lemmas 5.3.33, 5.3.34 and 5.3.35

**Corollary 5.3.36.** \( S' \) is a generalized hexagon of order \((st', \frac{t'}{t} - 1)\).

Since there is a unique generalized hexagon of order \((4, 1)\), we have proved Theorem 5.1.2 completely. For Theorem 5.1.1(1), we still need to check if the generalized hexagon \( S_1 \) of order 4 is isomorphic to the dual split Cayley hexagon \( H(4)^D \). This can be done easily in a computer model of \( S_1 \) using the geometrical characterization of dual Split Cayley hexagons obtained by Ronan [120].

### 5.4. Hall-Janko Suboctagons of \( O_1 \)

In this section, we construct and classify all Hall-Janko suboctagons of \( O_1 \). These are (full) subgeometries of \( O_1 \) that are isomorphic to \( HJ \). We will show that there are 416 such subgeometries and that all of them are isometrically embedded. In the following lemma, we already construct all these 416 subgeometries from the 416 (maximal) subgroups of \( G_2(4):2 \) isomorphic to \( J_2:2 \). But first we include some group theoretical properties of the group \( G_2(4):2 \) and \( J_2:2 \) that one can obtain from [54] and GAP.

The group \( G_2(4):2 \) has \( J_2:2 \) as a maximal subgroup of index 416. If we have \( H \cong J_2:2 \) and \( G \cong G_2(4):2 \) such that \( H < G \) and if \( \Sigma_H, \Sigma_G \) denote the corresponding conjugacy classes of central involutions, then \( \Sigma_H = H \cap \Sigma_G \). Moreover, \( \Sigma_H \subseteq G' \cong G_2(4) \). We also note that if \( x, y \) are two distinct commuting central involutions of \( H \), then \( [G : N_G(\langle x, y \rangle)] = 13650 \). Since \( \Sigma_G \) generates a normal subgroup of the simple group \( G' \), we necessarily have \( \langle \Sigma_G \rangle = G' \). Similarly, \( \langle \Sigma_H \rangle = H' \).

Also, \( N_G(H) = H \), and hence \( H \) has precisely 416 conjugates in \( G \). There exists a natural
bijective correspondence between the subgroups of \( G = G_2(4):2 \) isomorphic to \( J_2:2 \) and the subgroups isomorphic to \( J_2 \). Every subgroup isomorphic to \( J_2:2 \) contains a unique \( J_2 \)-subgroup, namely its derived subgroup. Conversely, every \( J_2 \)-subgroup \( H \) of \( G \) must be contained in a unique (maximal) subgroup isomorphic to \( J_2:2 \), the normalizer of \( H \) inside \( G \).

**Lemma 5.4.1.** (1) Let \( H \) be a (maximal) subgroup of \( G = G_2(4):2 \) isomorphic to \( J_2:2 \). Then the set \( \Sigma_H \) of the central involutions of \( G \) contained in \( H \) is a subspace of the near octagon \( O_1 \) on which the induced subgeometry, denoted by \( S_H \), is isomorphic to the Hall-Janko near octagon \( HJ \).

(2) If \( H_1 \) and \( H_2 \) are two distinct maximal subgroups of \( G \) isomorphic to \( J_2:2 \), then \( S_{H_1} \) and \( S_{H_2} \) are distinct subgeometries.

**Proof.** (1) On the set \( \Sigma_H \subseteq H' \cong J_2 \), a Hall-Janko near octagon \( S'_H \) can be defined by taking as lines all the sets \( \{x, y, xy\} \), where \( x \) and \( y \) are two distinct commuting elements of \( \Sigma_H \). Recall that if the elements \( x, y \in \Sigma_H \) commute, then \( [G : N_G(x, y)] = 13650 \), implying that \( \{x, y, xy\} \) is a line of \( O_1 \), with \( y \in O_{10}(x) \) (see Section 5.2). Conversely, if \( x, y \in \Sigma_H \) such that \( \{x, y, xy\} \) is a line of \( O_1 \), then \( x, y \) commute and hence \( \{x, y, xy\} \) is also a line of \( S'_H \).

(2) We need to show that \( H \) is uniquely determined by \( \Sigma_H \). The subgroup generated by \( \Sigma_H \) is a normal subgroup of \( H' \cong J_2 \) and hence coincides with \( H' \). Inside \( G = G_2(4) : 2 \), there is a unique subgroup isomorphic to \( J_2 : 2 \) that contains \( H' \cong J_2 \), namely its normalizer. Hence, \( H = N_G(\Sigma_H) \).

Before proceeding to prove that every Hall-Janko suboctagon is as described in Lemma 5.4.1, we first give an alternative proof of a result of De Wispelaere and Van Maldeghem.

**Lemma 5.4.2.** The geometry \( HJ^D \) has a full embedding in \( H(4) \).

**Proof.** Let \( H \) be a maximal subgroup of \( G = G_2(4):2 \) isomorphic to \( J_2:2 \). Then by Lemma 5.4.1, \( S_H \cong HJ \) is a full subgeometry of \( O_1 \). Note that no line of \( S_H \) is contained in the line spread \( S_1 \) of \( O_1 \) as pairs of collinear points \( x, y \) in \( S_H \) satisfy \( [G : N_G(x, y)] = 13650 \). Therefore, every line \( L \) of \( S_H \) is contained in a unique quad \( Q_L \) by Lemma 5.3.9. As any two involutions of \( Q_L \cap H \) commute, \( Q_L \cap H \) is at most a line of \( H \), implying that \( L = Q_L \cap H \). So, if \( L_1, L_2, \ldots, L_5 \) are the five lines of \( S_H \) through a given point \( x \), then the quads \( Q_{L_1}, Q_{L_2}, \ldots, Q_{L_5} \) are mutually distinct and hence are all the five quads through the line \( L_x \) of the spread \( S_1 \) (see Lemmas 5.3.4 and 5.3.8). This implies that the maps \( x \mapsto L_x, L \mapsto Q_L \) define a full embedding of the dual of \( S_H \) into the dual of \( (S_1, Q_1) \), which is isomorphic to \( H(4) \) (see Theorem 5.1.1(2)).

In the rest of this section, \( \mathcal{H} \) will denote an arbitrary Hall-Janko suboctagon, not necessarily arising from the central involutions contained in a Hall-Janko subgroup. We will derive several properties of \( \mathcal{H} \) that will enable us to prove that there are at most (and hence precisely) 416 Hall-Janko suboctagons of \( O_1 \). For \( x, y \in O_1 \), we simply denote \( d_{O_1}(x, y) \) by \( d(x, y) \).

**Lemma 5.4.3.** If \( x \) and \( y \) are two points of \( \mathcal{H} \) such that \( d_{\mathcal{H}}(x, y) \leq 2 \) then \( d_{\mathcal{H}}(x, y) = d(x, y) \).
Proof. Follows directly from the fact that $\mathcal{H}$ is a full subgeometry of the near polygon $O_1$.

**Lemma 5.4.4.** If $x$ and $y$ are two points of $\mathcal{H}$ such that $d_H(x, y) = d(x, y) = 3$ then $y \in O_{3b}(x)$.

**Proof.** Since $\mathcal{H}$ is a regular near octagon with parameters $(2, 4; 0, 3)$ there must be four lines of $\mathcal{H}$ through $y$ that contain a point at distance 2 from $x$ in $\mathcal{H}$ (and hence also in $O_1$ by Lemma 5.4.3). But, by the suborbit diagram, if $y$ lies in $O_{3b}(x)$ then there are are only three lines through $y$ containing a point at distance 2 from $x$ (see Figure 5.1). □

**Lemma 5.4.5.** Let $Q$ be a quad of $O_1$ and $x, y$ two points of $Q$ such that $d(x, y) = 2$. If $z$ is a point collinear with $y$ and not contained in $Q$ then $z \in O_{3a}(x)$.

**Proof.** As $z$ is classical with respect to $Q$, $d(x, z) = 3$. Now this directly follows from the suborbit diagram with respect to $x$ and Lemma 5.3.3. □

**Lemma 5.4.6.** A quad $Q$ of $O_1$ cannot contain a pair of intersecting lines of $\mathcal{H}$.

**Proof.** Suppose $L_1$ and $L_2$ are two intersecting lines of $\mathcal{H}$ contained in $Q$. Let $x_1 \in L_1 \setminus L_2$ and $x_2 \in L_2 \setminus L_1$. As there are five lines through $x_2$ contained in $\mathcal{H}$ and only three contained in $Q$, there exists a neighbor $x_3$ of $x_2$ in $\mathcal{H} \setminus Q$. For this point $x_3$, we have $d_H(x_1, x_3) = d(x_1, x_3) = 3$. By Lemma 5.4.5, $x_3 \in O_{3a}(x_1)$. This contradicts Lemma 5.4.4 which would imply that $x_3 \in O_{3b}(x_1)$. □

**Lemma 5.4.7.** None of the lines of the line spread $S_1$ is contained in $\mathcal{H}$.

**Proof.** Suppose $L$ is a line of $S_1$ contained in $\mathcal{H}$, and let $M$ denote any other line of $\mathcal{H}$ meeting $L$ in a point. By Lemmas 5.3.4 and 5.3.9, there is a unique quad $Q$ containing $L$ and $M$. This quad would contradict Lemma 5.4.6. □

**Lemma 5.4.8.** Every quad which contains a point $x$ of $\mathcal{H}$ contains a unique line of $\mathcal{H}$ through $x$.

**Proof.** By Lemma 5.4.7, the line $L_x$ is not contained in $\mathcal{H}$. There are five lines through $x$ contained in $\mathcal{H}$. By Lemma 5.4.6, each of the five quads through $L_x$ contains at most one and hence precisely one of these five lines. □

**Lemma 5.4.9.** $\mathcal{H}$ is isometrically embedded into $O_1$.

**Proof.** Suppose $d(x, y) \neq d_H(x, y)$ for certain points $x$ and $y$ of $\mathcal{H}$, and suppose $x$ and $y$ have been chosen in such a way that $i := d_H(x, y)$ is as small as possible. By Lemma 5.4.3, $i \in \{3, 4\}$. Let $y'$ be a point in $\mathcal{H}$ such that $d_H(x, y') = i - 1$, $d_H(y', y) = 1$ and let $y''$ denote the third point on the line $yy'$. By the near polygon property we know that $d_H(x, y'') = d(x, y) = i$. By the minimality of $i$, $d(x, y') = i - 1$. Again by the near polygon property, $\{d(x, y), d(x, y'')\} = \{i - 1, i - 2\}$. So, still under the assumption that the distance $d_H(x, y)$ is as small as possible, we could have chosen $y$ in such a way that $d(x, y) = d_H(x, y) - 2$.

Suppose $i = 3$. Then we have $x, y \in \mathcal{H}$ such that $d_H(x, y) = 3$ and $d(x, y) = 1$. Let $x, z_1, z_2, y$ be a shortest path between $x$ and $y$ in $\mathcal{H}$. By Lemma 5.4.3, $d(x, z_2) = 2$. Since $x$ and $z_2$ have at least two common neighbors in $\mathcal{G}$ (namely $y$ and $z_1$), there exists a quad $Q$ containing $x, z_2$ and all their common neighbors. The quad $Q$ would then contain the intersecting lines $xz_1$ and $z_1z_2$, which is in contradiction with Lemma 5.4.6. Therefore, if $x$ and $y$ are two points of $\mathcal{H}$ with $d_H(x, y) \leq 3$, then $d_H(x, y) = d(x, y)$.
Now suppose $i = 4$, i.e., we have $x, y \in \mathcal{H}$ such that $d_{\mathcal{H}}(x,y) = 4$ and $d(x,y) = 2$. Let $y'$ be a common neighbor of $x$ and $y$ in $O_1$. There exists a quad $Q$ through the line $xy'$ which by Lemma 5.4.8 must contain a line $M$ of $\mathcal{H}$ through $x$. Let $x'$ be the unique point on $M$ satisfying $d_{\mathcal{H}}(y,x') = 3$. From the previous case, we also have $d(y,x') = 3$. So, $y \in \mathcal{O}_{3b}(x')$ by Lemma 5.4.4. Since $d(y,x') = 3$, the quad $Q$ cannot contain the point $y$. \[\text{Lemma 5.4.5 (with } x, y \text{ and } z \text{ replaced by } x', y' \text{ and } y) \text{ would then imply that } y \in \mathcal{O}_{3a}(x'),\] which is in contradiction with the earlier claim that $y \in \mathcal{O}_{3b}(x')$. \[\square\]

**Lemma 5.4.10.** If $x$ and $y$ are two points of $\mathcal{H}$ such that $d_{\mathcal{H}}(x,y) = 2$ then $y \in \mathcal{O}_{2b}(x)$. 

**Proof.** We also have $d(x,y) = 2$. Let $x' \in \mathcal{H}$ be a common neighbor of $x$ and $y$. If $y \in \mathcal{O}_{2a}(x)$, then the unique quad through $x$ and $y$ would contain the intersecting lines $xx'$ and $x'y'$, which would be in violation with Lemma 5.4.6. \[\square\]

**Lemma 5.4.11.** Through every pair of opposite points of $O_1$ there is at most one Hall-Janko suboctagon. 

**Proof.** Let $x$ and $y$ be two opposite points of $O_1$ and suppose a Hall-Janko suboctagon $\mathcal{H}$ contains $x$ and $y$. We will show that $\mathcal{H}$ is uniquely determined by $x$ and $y$. In this proof all suborbits are considered with respect to the point $x$. By Lemma 5.4.9, the distance between two points of $\mathcal{H}$ is the same in the geometries $\mathcal{H}$ and $O_1$.

There are five lines through $y$ inside $\mathcal{H}$ that contain a point at distance 3 from $x$. By Lemma 5.4.4 all of these lines must intersect $\mathcal{O}_{3b}$. By the suborbit diagram and Lemma 5.3.17 there are exactly six such lines through $y$ and one of them is in the line spread $S_1$. By Lemma 5.4.7, the line belonging to $S_1$ cannot be contained in $\mathcal{H}$. Therefore the five lines of $\mathcal{H}$ through $y$, going back to $x$ are uniquely determined by $x$ and $y$.

Now let $y' \in \mathcal{O}_{3b}$ be a point on one of these five lines and $Q$ the unique quad through $yy'$ and $L_{y'} \neq yy'$. By Lemma 5.3.17 $L_{y'}$ meets $O_4$. By Lemma 5.4.8 the third line of $Q$ through $y'$, call it $M_{y'}$, doesn’t lie in $\mathcal{H}$. We claim that $M_{y'}$ intersects $\mathcal{O}_{2b}$. Indeed, as the point $x$ is classical with respect to $Q$, the unique point $u$ in $Q$ nearest to $x$ lies at distance 2 from $x$ and is collinear with $y'$. Therefore, $u \in \mathcal{O}_{2b}$ and $M_{y'} = y'u$. The four lines of $\mathcal{H}$ through $y'$ that go back to $x$ are now uniquely determined. Indeed, by Lemma 5.4.10 each of the four lines of $\mathcal{H}$ through $y'$ meets $\mathcal{O}_{2b}$. But by the suborbit diagram, there are precisely five such lines. Moreover, one of these five lines is the line $M_{y'}$ and we already know that it cannot be a line of $\mathcal{H}$.

Now, let $y'' \in \mathcal{O}_{2b}$ be a point on one of these four lines. By the suborbit diagram there is a unique line through $y''$ containing a point $y'''$ in $\mathcal{O}_{1b}$, which must necessarily be in $\mathcal{H}$. Moreover, there is a unique line through $y'''$ that contains $x$.

So far, we have proved that given any point $y$ in $\mathcal{H}$ with $d_{\mathcal{H}}(x,y) = 4$, all shortest paths between $x$ and $y$ in $\mathcal{H}$ are uniquely determined by $x$ and $y$. Moreover, all points at distance 4 from $x$ that are collinear with $y$ are uniquely determined. These properties in fact imply that the whole of $\mathcal{H}$ is uniquely determined. Indeed, the subgraph of the collinearity graph induced on the set $\Gamma_4(x) \cap \mathcal{H}$ is connected (see Step 1 of the proof of Theorem 3 in [53]), and every shortest path between $x$ and a point of $\mathcal{H}$ can be extended to a shortest path between $x$ and a point of $\Gamma_4(x) \cap \mathcal{H}$. \[\square\]

**Lemma 5.4.12.** There are precisely 416 Hall-Janko suboctagons of $O_1$, namely the suboctagons $\mathcal{S}_H$ for maximal subgroups $H \cong \mathbb{Z}_2^2 \cdot G = G_2(4):2$. Through every pair of opposite points of $G$, there is precisely one Hall-Janko suboctagon.
Proof. A Hall-Janko suboctagon has $315 \cdot 64$ ordered pairs of opposite points while $O_1$ has $4095 \cdot 2048$ such pairs. Therefore by Lemma 5.4.11 there are at most $(4095 \cdot 2048)/(315 \cdot 64) = 416$ Hall-Janko suboctagons in $O_1$. By Lemma 5.4.1 there are at least that many.

Now that we have classified all Hall-Janko sub near octagons of $O_1$, we end this section by proving some extra properties of these Hall-Janko suboctagons.

Lemma 5.4.13. If $H$ is a Hall-Janko suboctagon of $O_1$ and $x$ a point not contained in $H$, then there is a unique point $x'$ in $H$ that is collinear with $x$.

Proof. Let $H$ be a Hall-Janko suboctagon of $O_1$ and $x$ a point not contained in $H$. Say $x$ has two neighbors $y$, $z$ in $H$. Then by Lemma 5.4.9 $d_H(y,z) = 2$ and hence there is a common neighbor of $y$, $z$ inside $H$. This means that there is a quad through $y$, $z$ whose intersection with $H$ contains a pair of intersecting lines, contradicting Lemma 5.4.6. Therefore, if $x$ has a neighbor in $H$ then it has a unique neighbor.

Now we can show that $x$ has a neighbor in $H$ by a simple counting. There are six lines out of the eleven through each point in $H$ that are not contained in $H$, giving us a total of $12 \cdot 315$ points of $O_1$ at distance 1 from $H$. Adding this to the number of points in $H$ we get $315 \cdot 12 + 315 = 4095$ which is the total number of points in $O_1$. □

For a Hall-Janko suboctagon $H$ and a point $x$ of $O_1$ we define the projection of $x$ onto $H$, $\pi_H(x)$, to be $x$ if $x \in H$ and the unique point $x' \in H$ collinear with $x$ if $x \notin H$.

Lemma 5.4.14. Let $H$ be a Hall-Janko suboctagon of $O_1$ and $x$, $y$ be two distinct points not contained in $H$ such that $\pi_H(x) = \pi_H(y)$. Then $H \cap \Gamma_4(x) \neq H \cap \Gamma_4(y)$.

Proof. We consider the following two cases:

1. The point $x$ is collinear with $y$. Let $x' = \pi_H(x) = \pi_H(y)$ and $z \in \Gamma_4(x') \cap H$. Since $\{x, y, x'\}$ is a line, either $d(z, x) = 3$ and $d(z, y) = 4$, or $d(z, x) = 4$ and $d(z, y) = 3$. In either case $z$ belongs to only one of $H \cap \Gamma_4(x)$, $H \cap \Gamma_4(y)$.

2. The point $x$ is not collinear with $y$. Consider the suborbit diagram with $\omega$ equal to the common projection of $x$ and $y$.

Let $z$ be a point in $O_{3b} \cap H$. There are five lines through $z$ going back to $O_{2b}$ and four of them are contained in $H$. The one line that is not contained in $H$ gives us a unique point $z'$ of $O_{2b} \setminus H$ collinear with $z$. This in turn gives us a unique point $u$ in $O_{1b} \setminus H$ collinear with $\omega$ and $z'$. This point has distance 2 from $z$ and cannot belong to $H$ by Lemma 5.4.13.

Conversely, let $u$ be a point in $O_{1b} \setminus H$. It has sixteen neighbors in $O_{2b}$ none of which is contained in $H$ by Lemma 5.4.13. By the suborbit diagram and Lemma 5.4.4 the projection of each of these sixteen points in $H$ must lie in $O_{3b}$. Therefore, the ten points of $O_{1b} \setminus H$ partition the set $O_{3b} \cap H$, by the distance 2 map, into ten disjoint sets of size sixteen.

Without loss of generality, say $x \in O_{1b}$. Then the sixteen points of $O_{3b} \cap H$ that are at distance 2 from $x$ are at distance 4 from $y$. Indeed, if $z \in O_{3b} \cap H$ lies at distance 2 from $x$, then through $\omega$, there are precisely five lines containing a point at distance 2 from $z$. Four of these lines are contained in $H$ and the fifth line is $\omega x$. So, $y$ which is still on another line through $\omega$ should lie at distance 4 from $z$. □
We finish this section by proving that the near octagon $O_1$ is isomorphic to $S$ constructed using the valuation geometry of $HJ$, by taking the points of type $A$, $B$, $C$, and lines of type $AAA$, $ABB$, $ACC$, $BBC$, $CCC$, is isomorphic to the near octagon $O_1$ constructed using the central involutions of $G_2(4):2$.

**Proposition 5.4.15.** The near octagon $O_1$ is isomorphic to $S$.

**Proof.** Regard $HJ$ as a full subgeometry of $O_1$. Then $HJ$ is isometrically embedded into $O_1$ by Lemma 5.4.9. By Lemma 2.2.4, every point $x$ of $O_1$ will induce a valuation $f_x$ of $HJ$. This valuation is of Type $A$ if and only if $x$ belongs to $HJ$. By Lemma 5.4.13, each induced valuation has a unique point with value 0. So, all induced valuations have Type $A$, $B$ or $C$ by Table 2.7. By Lemma 5.4.14, all induced valuations are distinct, implying that the 4095 induced valuations are precisely the 4095 valuations of $HJ$ that have Type $A$, $B$ or $C$. Now, every point of $O_1$ is incident with precisely 11 lines. By looking at the columns “$A$” and “$C$” of Table 2.8 we see that all lines of $V$ of Type $AAA$, $ABB$, $ACC$, $BBC$ and $CCC$ should be induced by some line of $O_1$. The number of such lines of $S$ is equal to $\frac{3155}{3} + 315 \cdot 1 + 315 \cdot 5 + 3150 \cdot 1 + \frac{31509}{3} = 15015$. Since $O_1$ has $\frac{4095\cdot11}{3} = 15015$ lines, we see that the lines of $S$ that are induced are precisely the lines of Type $AAA$, $ABB$, $ACC$, $BBC$ and $CCC$. We can now conclude that $O_1$ and $S$ are isomorphic. 

## 5.5. The Automorphism Groups

### 5.5.1. Automorphism Group of $G_2(4)$ Near Octagon

**Lemma 5.5.1.** The group $G_2(4):2$ acts faithfully on points of $O_1$ as a group of automorphism of $O_1$, where the action on the point set (i.e. the central involutions) is given by conjugation.

**Proof.** Each $g \in G = G_2(4):2$ determines an automorphism of $O_1$: if $x$ is a central involution and $g \in G$, then $x^g = g^{-1}xg$ is again a central involution. We will show that this action is faithful. We have seen that the central involutions generate the group $G' = G_2(4)$. So the centralizer of the set of central involutions is equal to the centralizer of $G'$ in $G$, denoted by $C_G(G')$. Since $C_G(G')$ is a normal subgroup of $G$, and since $G'$ is simple, we must have $G' \cap C_G(G') = \{e\}$, where $e$ is the identity of $G$. So we have $|G'C_G(G')| = |G'||C_G(G')| \leq |G| = 2|G'|$. Which shows that either $C_G(G')$ is trivial or isomorphic to the cyclic group $C_2$. When it is trivial, the action is faithful. So, say it is not. Then we must have that $G$ is equal to the internal direct product of $G' \cong G_2(4)$ and $C_G(G') \cong C_2$, which is a contradiction to the fact that $G$ is a proper semi-direct product of $G_2(4)$ and $C_2$.

**Lemma 5.5.2.** Every automorphism $\theta$ of $O_1$ permutes the elements of the line spread $S_1$ and thus determines an automorphism of $(S_1, Q_1) \cong H(4)^D$.

**Proof.** The automorphism $\theta$ permutes the quads of $O_1$ and hence the lines of $O_1$ that can be obtained as intersections of two quads (these are precisely the elements of $S_1$).

**Lemma 5.5.3.** Suppose $\theta$ is an automorphism of $O_1$ fixing each line of $S_1$. Then $\theta$ is the identity.
Proof. Let \( x \) be an arbitrary point of \( O_1 \), \( L = \{x, y, z\} \) a line through \( x \) not belonging to \( S_1 \) and \( Q \) the unique quad through \( L \) (see Lemma 5.3.9). The lines of \( S_1 \) contained in \( Q \) determine a spread of \( Q \). Since \( Q \cong W(2) \), it is easily seen that \( L \) is the unique line of \( Q \) meeting the lines \( L_x, L_y \) and \( L_z \) of \( Q \) (see Figure 1.1). From \( L_x^\theta = L_x, L_y^\theta = L_y \) and \( L_z^\theta = L_z \), it then follows that \( x^\theta = x \). \( \square \)

**Proposition 5.5.4.** The full automorphism group of \( O_1 \) is isomorphic to \( G_2(4):2 \).

Proof. From Lemma 5.5.1 we see that \( G_2(4):2 \leq \text{Aut}(O_1) \). By Lemmas 5.5.2 and 5.5.3 we have \( |\text{Aut}(O_1)| \leq |\text{Aut}(H(4)^D)| = |G_2(4):2| \), which shows that there is equality. \( \square \)

It is possible to give another proof of Proposition 5.5.4 based on the following lemma.

**Lemma 5.5.5.** Let \( H \) be a subgroup of \( G_2(4):2 \) isomorphic to \( J_2:2 \). Then every automorphism \( \theta \) of \( S_H \cong HJ \) extends to precisely one automorphism of \( G \).

Proof. The action of \( \theta \) on the point set of \( S_H \) is given by conjugation by a suitable element of \( H \cong J_2:2 \). This conjugation also determines an automorphism of \( O_1 \). To show that \( \theta \) extends to at most one automorphism of \( G \), we must show that every automorphism \( \varphi \) of \( O_1 \) that fixes each point of \( S_H \) must be trivial. But this is directly implied by Lemma 5.4.14. \( \square \)

Since there are 416 Hall-Janko suboctagons (see Lemma 5.4.12), Lemma 5.5.5 implies that \( |\text{Aut}(O_1)| \leq 416 \cdot |\text{Aut}(HJ)| = 416 \cdot |J_2:2| = |G_2(4):2| \). Lemma 5.5.1 then again implies that \( \text{Aut}(O_1) \cong G_2(4):2 \). In fact, this reasoning also gives that the automorphism group is transitive on the Hall-Janko suboctagons, but we already knew this in advance as all maximal subgroups isomorphic to \( J_2:2 \) are conjugate.

### 5.5.2. Automorphism Group of \( \text{L}_3(4) \) Near Octagon

In this section we prove that the automorphism group of the \( \text{L}_3(4) \) near octagon \( O_2 \) is isomorphic to the group \( \text{L}_3(4):2^2 \). Consider the chain \( \text{L}_3(4) < \text{L}_3(4):2 < \text{L}_3(4):D_{12} \) of groups and their actions on the sets of points and lines of the projective plane \( \text{PG}(2,4) \) (as described in Section 5.2.2). Recall that \( \text{L}_3(4):D_{12} \) consists of all collineations and correlations of \( \text{PG}(2,4) \). Let \( \Sigma \) denote the set of all central involutions of the groups \( \text{L}_3(4):2^2 \), or equivalently, of \( \text{L}_3(4) \). Then every element of \( \Sigma \) is a nontrivial elation of \( \text{PG}(2,4) \). From Lemma 5.2.2 it follows that the action of the group \( \text{L}_3(4):D_{12} \), and hence of the group \( \text{L}_3(4):2^2 \), on the elations via conjugation is faithful. Just as in Lemma 5.5.1, we see that this action of \( \text{L}_3(4):2^2 \) gives us \( \text{Inn}(\text{L}_3(4):2^2) \cong \text{L}_3(4):2^2 \leq \text{Aut}(O_2) \).

We will now show that the size of the automorphism group is at most \( 4|\text{L}_3(4)| \), thus proving equality. Of course, this can be checked in a computer using SageMath, which can easily compute the automorphism group of the collinearity graph of this near octagon (see Lemma 1.3.2), but we prefer to give a computer free proof.

**Lemma 5.5.6.** Every automorphism \( \theta \) of \( O_2 \) permutes the elements of the line spread \( S_2 \) and thus determines an automorphism of \( (S_2, Q_2) \cong H(4,1) \).

Proof. The proof is similar to that of Lemma 5.5.2. \( \square \)

**Lemma 5.5.7.** Let \( Q \) be a quad of \( O_2 \) and \( L_1, \ldots, L_5 \) the five lines of the line spread \( S_2 \) which are contained in \( Q \). If \( \theta \) is an automorphism of \( O_2 \) which fixes each of these lines, then \( \theta \) fixes each point of \( Q \).
Proof. Let $x$ be an arbitrary point of $Q$, and $L = \{x, y, z\}$ a line of $Q$ through $x$ which is not contained in $S_2$. Then since $Q$ is isomorphic to $W(2)$, $L$ is the unique line of $Q$ which intersects the lines $L_x, L_y, L_z \in S_2$ of $Q$. As $L_x^\theta = L_x, L_y^\theta = L_y$ and $L_z^\theta = L_z$, we must have $L^\theta = L$ and in particular $x^\theta = x$. \hfill \Box

Corollary 5.5.8. If $\theta$ is an automorphism of $O_2$ which fixes every line in $S_2$, then $\theta$ fixes every point of $O_2$. Consequently, the action of $\text{Aut}(O_2)$ on $(S_2, Q_2) \cong H(4,1)$ is faithful.

As a result of Corollary 5.5.8, we can look at $\text{Aut}(O_2)$ as a subgroup of $\text{Aut}(H(4,1)) \cong L_3(4):D_{12}$. Denote the geometry $(S_2, Q_2) \cong H(4,1)$ by $\mathcal{S}$. Note that if $(x, L)$ is a flag of $\mathcal{S}$, then the non-trivial elations which have center $x$ and axis $L$ form an element of the line spread $S_2$ in the near octagon $O_2$ constructed using these elations. For a point $x$ of $PG(2,4)$ let $C_x$ denote the set of all (non-trivial) elations with center $x$, and for a line $L$ let $C_L$ denote the set of all (non-trivial) elations with axis $L$. Then these sets correspond bijectively to the quads of $O_2$, i.e., the lines of $\mathcal{S}$. What we have shown is that every automorphism of $\mathcal{S}$ which corresponds to either a collineation or a correlation of $PG(2,4)$, gives rise to at most one automorphism of $O_2$, and we have a subgroup $H \cong \text{Aut}(O_2)$ of this group $G$ of all collineations and correlations of $PG(2,4)$, and the latter has type $L_3(4):D_{12}$. We will show that there exists a subgroup $H'$ of $G$ such that $|H'| = 3$ and $H \cap H' = \{e\}$, thus proving $|H| \leq |G|/|H'| \leq 4|L_3(4)|$ (recall that for any two subgroups $H_1, H_2$ of a finite group we have $|H_1 H_2| = |H_1||H_2|/|H_1 \cap H_2|$).

Lemma 5.5.9. Let $Q$ be a quad of $O_2$ and let $L_1, \ldots, L_5$ be lines of the spread $S_2$ which are contained in $Q$. Let $\theta$ is an automorphism of $O_2$ such that $L_1^\theta = L_1, L_2^\theta = L_2, L_3^\theta = L_4, L_4^\theta = L_5$ and $L_5^\theta = L_3$, then $\theta$ permutes the points of $L_1$ according to a cycle of length 3.

Proof. Since $Q$ is isomorphic to $W(2)$, we know that if $x \in L_1$ and $y \in L_2$ are collinear, then there is a unique $i \in \{3, 4, 5\}$ for which $L_i$ intersects the lines $xy$. Now for each $i \in \{3, 4, 5\}$, choose the collinear points $x_i \in L_1$ and $y_i \in L_2$ for which the line $M_i = x_i y_i$ intersects the line $L_i$. Then we must have $M_3^\theta = M_4, M_4^\theta = M_5$ and $M_5^\theta = M_3$. Thus, the points $x_3, x_4$ and $x_5$ of $L$ are permuted according to a cycle of length 3. \hfill \Box

Let $\sigma$ be a nonidentity homology of $PG(2,4)$, i.e., a collineation which fixes all points on a line $L$ (the axis of $\sigma$) and all lines through a point $x \not\in L$ (the center of $\sigma$). Then $\sigma$ generates a cyclic group of order 3, which is a subgroup $H'$ of $G$.

Lemma 5.5.10. Let $\sigma$ be a homology of $PG(2,4)$ that has center $x$ and axis $L$, and let $H'$ be the subgroup of $G \cong L_3(4):D_{12}$ generated by $\sigma$. Then, we have $H \cap H' = \{e\}$.

Proof. Suppose $\theta \in H \cap H' \setminus \{e\}$ is induced by an automorphism $\theta$ of the near octagon $O_2$. Let $Q_1$ be the quad of $O_2$ corresponding to the line $L$ and let $Q_2$ be the quad of $O_2$ corresponding to a point $y$ on $L$. Then $Q_1 \cap Q_2$ is the line of $S_2$ corresponding to the flag $(y, L)$ of $PG(2,4)$. Since $\theta$ is a homology with axis $L$ it fixes every point on $L$, and therefore $\theta$ fixes every line of $S_2$ contained in the quad $Q_1$. So, by Lemma 5.5.7, $\theta$ fixes every point in $Q_1 \cap Q_2$. Since $\theta$ fixes the point $x$ and $y$, it fixes the line $M = xy$, and since it’s a homology, it permutes the three lines through $y$ other than $M$ and $L$ in a cycle of length 3. This implies that $\theta$ fixes two lines of $S_2$ contained in $Q_2$ (the line corresponding to $(y, M)$ and the line corresponding to $(y, L)$), and permutes the remaining three lines in a cycle of length 3. This contradicts Lemma 5.5.9 as $\theta$ fixes the line $Q_1 \cap Q_2$ pointwise. \hfill \Box

We have thus proved the following.

Proposition 5.5.11. The full automorphism group of $O_2$ is isomorphic to $L_3(4):2^2$. 
5.6. Distance Regular Graphs of Soicher

In [129], Soicher constructed distance regular graphs $\Sigma$, $\Upsilon$ and $\Delta$ with intersection arrays $\{416,315,64,1;1,32,315,416\}$, $\{56,45,16,1;1,8,45,56\}$ and $\{32,27,8,1;1,4,27,32\}$, respectively. It is clear from the intersection arrays, that all of these graphs have diameter 4. The graph $\Sigma$ is a triple cover of the Suzuki graph (in the sense of [129]) and has $\text{Aut}(\Sigma) \cong 3 \cdot \text{Suz}:2$. Under the action of the stabilizer (which is isomorphic to $G_2(4):2$) of its automorphism group with respect to a vertex $x$, the orbits are equal to $\Sigma_0(x)$, $\Sigma_1(x)$, $\Sigma_2(x)$, $\Sigma_3(x)$ and $\Sigma_4(x)$, with sizes 1, 416, 4095, 832 and 2, respectively (so in particular, the graph $\Sigma$ is distance transitive). We will show in Section 5.6.1 we can construct the near octagon $O_1$ using the graph $\Sigma$, and that the subgraph of $\Sigma$ induced on $\Sigma_3(x)$ is isomorphic to the graph defined on the points of $O_1$ where two points are adjacent when they are at distance 2 and have a unique common neighbor. Soicher has recently proved that the graph $\Delta$ is the unique distance regular graph with the given intersection array [131].

The graph $\Upsilon$ is a triple cover of the unique strongly regular graph of parameters $(162, 56, 10, 24)$ and its automorphism group also acts distance transitively on its vertices with the stabilizer with respect to a vertex isomorphic to $L_2(4)$:2, and suborbits of sizes 1, 56, 315, 112 and 2. In Section 5.6.2, we will construct the near octagon $O_1$ from this graph. The third graph $\Delta$ is simply the second subconstituent of $\Upsilon$, i.e., the graph induced on $\Upsilon_2(x)$ for any vertex $x$, and we will show that it is isomorphic to the graph obtained from the points of $O_2$ by making two points adjacent when they are at distance 2 from each other and have a unique common neighbor.

5.6.1. The First Graph

Let $x$ be a fixed point of $\Sigma$. The local graph $\Sigma_x$, i.e., the subgraph induced on the vertices set $\Sigma_1(x)$ of vertices adjacent to $x$, is isomorphic to the well-known $G_2(4)$-graph, which is a strongly regular graph with parameters $(v,k,\lambda,\mu) = (416,100,36,20)$. Let $G = \text{Aut}(\Sigma)$. Then the stabilizer $G_x$ is isomorphic to the group $G_2(4):2$, and it is the full automorphism group of the local graph of $\Sigma$. Recall that $O_1$ was constructed using the central involutions (which is a point of $O_1$) fixes 32 points of the $G_2(4)$-graph, which we denote by $X_\sigma$. Moreover, the elements of $X_\sigma$ determine the involution $\sigma$ uniquely, as the group generated by $\sigma$ is the unique subgroup of $G_2(4):2$ which fixes $X_\sigma$ pointwise. Therefore, the 4095 points of $O_1$ are in bijective correspondence with 4095 such special 32-sets in the $G_2(4)$-graph. We also record some information about these special sets in Table 5.3 with respect to the suborbits of $G_2(4)$ near octagon.

| $\sigma_2 \in \mathcal{O}_0(\sigma_1)$ | $X_{\sigma_1} = X_{\sigma_2}$ | $\sigma_2 \in \mathcal{O}_{2b}(\sigma_1)$ | $|X_{\sigma_1} \cap X_{\sigma_2}| = 8$ |
|---------------------------------|--------------------------|---------------------------------|-------------------------------|
| $\sigma_2 \in \mathcal{O}_{1a}(\sigma_1)$ | $X_{\sigma_1} \cap X_{\sigma_2} = \emptyset$ | $\sigma_2 \in \mathcal{O}_{3u}(\sigma_1)$ | $X_{\sigma_1} \cap X_{\sigma_2} = \emptyset$ |
| $\sigma_2 \in \mathcal{O}_{1b}(\sigma_1)$ | $|X_{\sigma_1} \cap X_{\sigma_2}| = 16$ | $\sigma_2 \in \mathcal{O}_{3b}(\sigma_1)$ | $|X_{\sigma_1} \cap X_{\sigma_2}| = 5$ |
| $\sigma_2 \in \mathcal{O}_{2a}(\sigma_1)$ | $X_{\sigma_1} \cap X_{\sigma_2} = \emptyset$ | $\sigma_2 \in \mathcal{O}_4(\sigma_1)$ | $|X_{\sigma_1} \cap X_{\sigma_2}| = 1$ |

Table 5.3: Fixed set intersections in the $G_2(4)$ near octagon
In Soicher’s graph Σ we can computationally check that for every vertex \( y \in Σ_2(x) \), the set \( Σ_1(x) \cap Σ_1(y) \) is a special 32-set of the \( G_2(4) \)-graph induced on \( Σ_1(x) \), i.e., there exists a unique central involution \( σ_y \) of \( G_2(4):2 \) which fixes this set \( X_y \) pointwise. In this manner, we get a map \( y \mapsto σ_y \) between the 4095 elements of \( Σ_2(x) \) and the 4095 central involutions of \( G_2(4):2 \) which is bijective. Moreover, computations in the graph Σ give us the following information for two points \( y_1, y_2 \in Σ_2(x) \) with \( S = Σ_1(y_1) \cap Σ_1(y_2) \), recorded in Table 5.4.

Table 5.4.: Intersection patterns in Soicher’s first graph

From Tables 5.3 and 5.4, it follows that for two vertices \( y_1, y_2 \in Σ_2(x) \), the involutions \( σ_y \) and \( σ_{y_2} \) are collinear in the near octagon \( O_1 \) (which is equivalent to \( σ \in O_{1a}(2) \cup O_{1b}(2) \)) if and only if \( S_1(y_1, y_2) = 4 \) or \( |Σ_1(x) \cap Σ_1(y_1) \cap Σ_1(y_2)| = 16 \) (and thus \( S_1(y_1, y_2) = 2 \)). From the discussion so far, we have the following.

**Theorem 5.6.1.** Let \( x \) be a fixed vertex of \( Σ \).

1. Let \( Γ \) denote the graph defined on the set \( Σ_2(x) \) of vertices at distance 2 from \( x \) in \( Σ \), by making two vertices \( y_1, y_2 \) adjacent if and only if \( S_1(y_1, y_2) = 4 \) or \( |Σ_1(x) \cap Σ_1(y_1) \cap Σ_1(y_2)| = 16 \). Then \( Γ \) is isomorphic to the collinearity graph of the \( G_2(4) \) near octagon \( O_1 \).

2. The subgraph of \( Σ \) induced on the vertex set \( Σ_2(x) \) is isomorphic to the graph defined on the points of the \( G_2(4) \) near octagon by making two points adjacent when they are at distance 2 and have a unique common neighbor.

### 5.6.2. The Second Graph

A similar analysis can be done for the second graph \( Υ \). Its local graph is isomorphic to the Gewirtz graph, which is the unique strongly regular graph with parameters \((56,10,0,2)\) [31]. Again, the stabilizer at a vertex of \( Υ \) is isomorphic to \( L_3(4):2^2 \), which is also the automorphism group of the Gewirtz graph. For every central involution \( σ \) of \( L_3(4):2^2 \), there is special 8-set \( X_σ \) consisting of the points of Gewirtz graph that are left fixed by this involution. The map \( σ \mapsto X_σ \) is a bijection between the 315 vertices of the \( L_3(4) \) near octagon \( O_2 \) and the 315 special 8-sets in the Gewirtz graph. Fix a vertex \( x \) in the graph \( Υ \). Then it can be checked computationally that for every vertex \( y \in Υ_2(x) \), the set \( Υ_1(x) \cap Υ_1(y) \) is a special 8-set of the local graph at \( x \). The information regarding the special sets and intersection patterns in this case is given in Tables 5.5 and 5.6 from which the following result follows.
Two New Near Octagons

\[ \sigma_2 \in \mathcal{O}_0(\sigma_1) \quad X_{\sigma_1} = X_{\sigma_2} \quad \sigma_2 \in \mathcal{O}_{2b}(\sigma_1) \quad |X_{\sigma_1} \cap X_{\sigma_2}| = 2 \]

\[ \sigma_2 \in \mathcal{O}_{1a}(\sigma_1) \quad X_{\sigma_1} \cap X_{\sigma_2} = \emptyset \quad \sigma_2 \in \mathcal{O}_{3a}(\sigma_1) \quad X_{\sigma_1} \cap X_{\sigma_2} = \emptyset \]

\[ \sigma_2 \in \mathcal{O}_{1b}(\sigma_1) \quad |X_{\sigma_1} \cap X_{\sigma_2}| = 4 \quad \sigma_2 \in \mathcal{O}_{3b}(\sigma_1) \quad |X_{\sigma_1} \cap X_{\sigma_2}| = 2 \]

\[ \sigma_2 \in \mathcal{O}_{2a}(\sigma_1) \quad X_{\sigma_1} \cap X_{\sigma_2} = \emptyset \quad \sigma_2 \in \mathcal{O}_4(\sigma_1) \quad |X_{\sigma_1} \cap X_{\sigma_2}| = 1 \]

Table 5.5.: Fixed set intersections in \( L_3(4) \) near octagon

\[
\begin{array}{|c|c|c|c|c|}
\hline
y_2 \in \mathcal{O}_0(y_1) & d_\Upsilon(y_1, y_2) & |\Upsilon_1(x) \cap S| & |\Upsilon_2(x) \cap S| & |\Upsilon_3(x) \cap S| \\
\hline

\hline
y_2 \in \mathcal{O}_{1b}(y_1) & 2 & 4 & 0 & 0 \\
\hline
y_2 \in \mathcal{O}_{2a}(y_1) & 2 & 4 & 0 & 0 \\
\hline
y_2 \in \mathcal{O}_{2b}(y_1) & 1 & 2 & 4 & 4 \\
\hline
y_2 \in \mathcal{O}_{3a}(y_1) & 3 & 0 & 0 & 0 \\
\hline
y_2 \in \mathcal{O}_{3b}(y_1) & 2 & 2 & 4 & 2 \\
\hline
y_2 \in \mathcal{O}_4(y_1) & 2 & 1 & 4 & 3 \\
\hline
\end{array}
\]

Table 5.6.: Intersection patterns in Soicher’s second graph

\textbf{Theorem 5.6.2.} Let \( x \) a fixed vertex of \( \Upsilon \).

(1) Let \( \Gamma \) denote the graph defined on the set \( \Upsilon_2(x) \) of vertices at distance 2 from \( x \) in \( \Upsilon \), by making two vertices \( y_1, y_2 \) adjacent if and only if \( d_\Upsilon(y_1, y_2) = 4 \) or \( |\Upsilon_1(x) \cap \Upsilon_1(y_1) \cap \Upsilon_1(y_2)| = 4 \). Then \( \Gamma \) is isomorphic to the collinearity graph of the \( L_3(4) \) near octagon \( O_2 \).

(2) The subgraph of \( \Upsilon \) induced on the vertex set \( \Upsilon_2(x) \) (which is the third distance regular graph of Soicher, \( \Delta \)) is isomorphic to the graph defined on the points of the \( L_3(4) \) near octagon by making two points adjacent when they are at distance 2 and have a unique common neighbor.
6. Suzuki Tower of Near Polygons

6.1. Introduction

The Suzuki tower is the sequence of five finite simple groups $L_3(2) < U_3(3) < J_2 < G_2(4) < Suz$ where each group, except the last one, is a maximal subgroup of the next group in the sequence. The five groups in the Suzuki tower correspond to five vertex-transitive graphs $\Gamma_0, \Gamma_1, \Gamma_2, \Gamma_3, \Gamma_4$ where the automorphism groups of the $\Gamma_i$’s are $L_3(2):2$, $U_3(3):2$, $J_2:2$, $G_2(4):2$ and $Suz:2$, respectively [132], [140, Section 5.6]. The graph $\Gamma_0$ is the complement of the incidence graph of Fano plane, i.e., the quartic vertex transitive co-Heawood graph, and the rest of them are strongly regular graphs having the following parameters $(v, k, \lambda, \mu)$:

- $\Gamma_1$: $(36, 14, 4, 6)$, the $U_3(3)$-graph;
- $\Gamma_2$: $(100, 36, 14, 12)$, the Hall-Janko graph;
- $\Gamma_3$: $(416, 100, 36, 20)$, the $G_2(4)$-graph;
- $\Gamma_4$: $(1782, 416, 100, 96)$, the Suzuki graph.

With the near octagon $O_1$ that we constructed in Chapter 5, we now also have a “tower” of near polygons

$$H(2, 1) \subset H(2)^D \subset HJ \subset O_1,$$

with automorphism groups $L_3(2):2$, $U_3(3):2$, $J_2:2$ and $G_2(4):2$, respectively. Thus we can call this the “Suzuki tower of near polygons”. Moreover, we will see in this chapter that the five graphs $\Gamma_0, \ldots, \Gamma_4$ can be constructed in a uniform fashion using these four near octagons, as follows: Let $S_0, S_1, S_2, S_3$ be the Suzuki tower near polygons and $\Gamma_0, \Gamma_1, \Gamma_2, \Gamma_3, \Gamma_4$ the graphs of the Suzuki tower. We define $S_{-1}$ to be the partial linear space on nine points and four lines obtained from the $(3 \times 3)$-grid by removing two disjoint lines (and keeping the points incident with these two lines).

**Theorem 6.1.1.** The complement of $\Gamma_i$ with $i \in \{0, 1, 2, 3\}$ is isomorphic to the graph whose vertices are the subgeometries of $S_i$ isomorphic to $S_{i-1}$, where two distinct subgeometries are adjacent whenever they intersect in the perp of a point.

For $i \in \{0, 1, 2\}$ the statement of Theorem 6.1.1 was already known in the literature (thought without any mention of the Suzuki tower of near polygons), but for $i = 3$ our result is new. While we do not give a construction of $\Gamma_4$ in a similar fashion, we can translate the original construction by Suzuki [132] in near polygon language as follows.

**Theorem 6.1.2.** Define a graph as follows:

\footnote{a name coined by Tits, as it has been mentioned in [101]}

\[\text{The complement of } \Gamma_i \text{ with } i \in \{0, 1, 2, 3\} \text{ is isomorphic to the graph whose vertices are the subgeometries of } S_i \text{ isomorphic to } S_{i-1}, \text{ where two distinct subgeometries are adjacent whenever they intersect in the perp of a point.} \]
take the elements of \( \{\infty\} \), \( A \) and \( B \) as vertices, where \( \infty \) is just a symbol, \( A \) is the set of all Hall-Janko suboctagons of the near octagon \( O_1 \) and \( B \) is the line spread \( S_1 \) of \( O_1 \);

• join \( \infty \) to all vertices in \( A \), join two distinct vertices of \( A \) if the corresponding suboctagons intersect in a subhexagon isomorphic to \( H(2)^D \), join a vertex of \( A \) to all the vertices in \( B \) that correspond to a line intersecting the suboctagon, join two vertices in \( B \) if the corresponding lines are at distance 2 from each other in the near octagon.

Then this graph is isomorphic to the Suzuki graph.

We will prove Theorems 6.1.1 and 6.1.2 in Section 6.2.

Remark. (1) We note that there are various other geometries associated with the Suzuki tower that have been studied before, see for example [112], [128] and [101].

(2) We do not know if there is a near polygon which corresponds to \( \text{Suz} \), but certainly the involution geometry of \( \text{Suz} \) studied in the literature [16,141] is not a near polygon; we can directly see from the suborbit diagram [16, Fig. 1] that there are point-line pairs \((p, L)\) in this geometry where every point of the line \( L \) is at the same distance 4 from \( p \). However, this involution geometry is a near 9-gon in the sense of [34, Sec. 6.4]. Indeed, it is clear from the suborbit diagram [16, Fig. 1] that the geometry has diameter 4 and that for every point-line pair \((p, L)\) with \( d(p, L) < 4 \), there is a unique point on \( L \) nearest to \( p \). Similarly, one can verify that the involution geometry of the Conway group \( \text{Co}_1 \) [17, Fig. 1] which contains \( \text{Suz} \) is a near 11-gon. The techniques involving valuations of near polygons used in this thesis do not work for near \((2d+1)\)-gons, and thus we are unable to give similar characterizations of these involution geometries. We do not know if there are more near polygons hiding in larger groups that can extend the Suzuki tower of near polygons (see [128] for a possible extension of the Suzuki tower of groups).

For all \( i \in \{1, 2, 3, 4\} \) the graph \( \Gamma_i \) contains \( \Gamma_{i-1} \) as a local graph, i.e., the graph induced on the neighborhood of any vertex of \( \Gamma_i \) is isomorphic to \( \Gamma_{i-1} \). In fact, it has been proved in [115] that for \( i \in \{2, 3\} \) the graph \( \Gamma_i \) is the unique connected graph which is locally \( \Gamma_{i-1} \), while there exist two connected graphs which are locally \( \Gamma_3 \), the graph \( \Gamma_4 \) and the graph \( 3\Gamma_4 \) constructed by Soicher [129] which is a 3-fold antipodal cover of the Suzuki graph \( \Gamma_4 \). In [36], it was proved that there are up to isomorphism three connected graphs that are locally \( \Gamma_0 \), one of which is the \( U_3(3) \)-graph \( \Gamma_1 \). Motivated by these characterization of the graphs in the Suzuki tower, we give some characterizations of the geometries in the Suzuki tower of near polygons by proving the following three theorems.

**Theorem 6.1.3.** The dual split Cayley hexagon of order 2 is the unique near hexagon of order \((2, 2)\) that contains the generalized hexagon \( H(2, 1) \) as an isometrically embedded subgeometry.

**Theorem 6.1.4.** The Hall-Janko near octagon is the unique near octagon of order \((2, 4)\) that contains the dual split Cayley hexagon of order \((2, 2)\) as an isometrically embedded subgeometry.

**Theorem 6.1.5.** The \( \text{G}_2(4) \) near octagon is the unique near octagon of order \((2, 10)\) that contains the Hall-Janko near octagon as an isometrically embedded subgeometry.
The proof of Theorem 6.1.3 already follows from the results of Section 1.3.2. It is folklore that \( H(2) \) does not containing any subhexagons isomorphic to \( H(2,1) \). Therefore, it suffices to show that \( \mathbb{L}_3 \times \mathbb{L}_3 \times \mathbb{L}_3 \) does not contain any subgeometry isomorphic to \( H(2,1) \). So, let \( \mathcal{H}_1 \cong H(2,1) \) be a subgeometry of \( \mathcal{H}_2 \cong \mathbb{L}_3 \times \mathbb{L}_3 \times \mathbb{L}_3 \). We know that \( \mathcal{H}_1 \) has 21 points and \( \mathcal{H}_2 \) has 27 points. Each point of \( \mathcal{H}_1 \) is collinear with exactly two points of \( \mathcal{H}_2 \setminus \mathcal{H}_1 \). Since \( |\mathcal{H}_2 \setminus \mathcal{H}_1| = 6 \), there must be a point in \( \mathcal{H}_2 \setminus \mathcal{H}_1 \) collinear with at least \( (21 \cdot 2)/6 = 7 \) points of \( \mathcal{H}_1 \). This contradicts the fact that \( \mathcal{H}_2 \) has order \( (2,2) \), and thus we have proved Theorem 6.1.3. We will prove Theorems 6.1.4 and 6.1.5 in Section 6.3 using the theory of valuations described in Chapter 2.

### 6.2. Constructing the Graphs

We first review the original construction of the Suzuki Tower graphs \(^{132}\) (see also \(^{115}\)). The graph \( \Gamma_0 \) is simply the complement of the incidence graph of the Fano plane \( \text{PG}(2,2) \), which clearly has automorphism group \( \mathbb{L}_3(2):2 \). Let \( \Delta = \Gamma_{i-1}, \Gamma = \Gamma_i \) and \( H = \text{Aut}(\Delta) \) for some \( i \in \{1,2,3,4\} \). The graph \( \Gamma \) is then constructed from the graph \( \Delta \) as follows.

Let \( S \) be the conjugacy class of 2-subgroups (involutions) of \( H \) of type \( 2A \) (in ATLAS notation) if \( i \in \{1,2,3\} \). In the remaining case, \( i = 4 \), let \( S \) be the conjugacy class of \( 2^2 \)-subgroups of \( H \) generated by \( 2A \)-involutions \( x \) and \( y \) which satisfy the condition \( [H : N_H(\langle x,y \rangle)] = 1365 \). Let \( \infty \) be an extra symbol, which is not contained in \( S \) or the set of vertices \( V(\Delta) \) of the graph \( \Delta \). Then the vertex set of \( \Gamma \) is \( V(\Gamma) = \{\infty\} \cup V(\Delta) \cup S \), and adjacencies are defined as:

(a) the vertex \( \infty \) is made adjacent to all the elements of \( V(\Delta) \);

(b) two vertices in \( V(\Delta) \) are adjacent if they are adjacent as vertices of \( \Delta \);

(c) a vertex \( x \in S \) is adjacent to a vertex \( v \in V(\Delta) \) if a non trivial element of the subgroup corresponding to \( x \) fixes \( v \);

(d) two vertices \( x, y \) in \( S \) are adjacent if \( x, y \) considered as subgroups of \( H \) do not commute but there exists a \( z \in S \) that commutes with both of them.

While the construction seems “asymmetric”, the group \( \text{Aut}(\Gamma) \) acts transitively on the vertices. Also, for each \( i \in \{1,2,3,4\} \), the group \( G_{i-1} = \text{Aut}(\Gamma_{i-1}) \) is the stabilizer of the group \( G_i = \text{Aut}(\Gamma_i) \) at a vertex. Moreover, \( G_{i-1} \) is a maximal subgroup of \( G_i \) of index \( |\Gamma_i| \). We have \( G_0 \cong \mathbb{L}_3(2):2, G_1 \cong G_2(2), G_2 \cong J_2:2, G_3 \cong G_2(4):2 \) and \( G_4 \cong \text{Suz}:2 \).

In the construction of the near octagon \( O_1 \) in Chapter 5 we saw that the \( 2^2 \)-subgroups of \( G = G_2(4):2 \) which are generated by \( 2A \) involutions \( x, y \) satisfying \( [G : N_G(\langle x,y \rangle)] = 1365 \), correspond (bijectively) to the lines of \( O_1 \) which are contained in the line spread \( S_1 \). Moreover, in the \( G_2(4) \) graph we can check that two vertices are adjacent if and only if the corresponding \( J_2:2 \) subgroups (stabilizers of the vertices) intersect in a \( G_2(2) \) subgroup. Also recall the correspondence between \( J_2 \) subgroups of \( G_2(4) \) and the \( J_2:2 \) subgroups of \( G_2(4):2 \) described in Section 5.4. Therefore, the \( G_2(4) \)-graph is the graph whose vertices are the maximal subgroup of \( G_2(4) \) isomorphic to \( J_2 \) where two Hall-Janko subgroups are adjacent whenever they intersect in a subgroup isomorphic to \( G_2(2) \cong \text{U}_3(3) \).

\(^{2}\)A proof of this can be given by checking that if \( H(1,2) \) is contained in \( H(2)^D \) then one can get an intersecting set in the sense of \(^{120}\) of size 1, which contradicts \(^{120}\) Corollary 1.2.]
Lemma 6.2.1. The $G_2(4)$-graph $\Gamma_3$ is isomorphic to the graph $\Gamma'$ whose vertices are the Hall-Janko suboctagons of $O_1$, where two Hall-Janko suboctagons are adjacent whenever they intersect in a subgeometry isomorphic to $H(2)^D$.

Proof. It is well-known that the Hall-Janko near octagon $HJ$ has 100 subhexagons isomorphic to $H(2)^D$ (see for example [30]), and that these are in bijective correspondence with the 100 maximal subgroups of $J_2$ isomorphic to $G_2(2)'$ (just like the $J_2$ subgroups of $G_2(4)$ correspond to the Hall-Janko near octagons of the $G_2(4)$ near octagon). The points of a subhexagon are the central involutions contained in the corresponding maximal subgroup. Moreover, these central involutions generate the maximal subgroup.

For every subgroup $H$ of $G_2(4)$, denote by $\Sigma_H$ the set of central involutions which are contained in $H$. If $H \cong J_2$, then the geometry $S_H$ induced on the subspace $\Sigma_H$ of $O_1$ is isomorphic to $HJ$. By Lemma 5.4.12 the map $H \mapsto S_H$ defines a bijection between the 416 maximal subgroups of $G_2(4)$ isomorphic to $J_2$ and the 416 Hall-Janko suboctagons of $O_1$. We show that this map defines an isomorphism between the $G_2(4)$-graph and the graph $\Gamma'$.

Take two mutually distinct subgroups $H_1$ and $H_2$ of $G_2(4)$ isomorphic to $J_2$. If $H_1$ and $H_2$ are two adjacent vertices of the $G_2(4)$-graph, then the subgeometries $S_{H_1}$ and $S_{H_2}$ intersect in a subgeometry whose point set is $\Sigma_{H_1} \cap \Sigma_{H_2} = \Sigma_{H_1 \cap H_2}$, i.e. in a subgeometry isomorphic to $H(2)^D$ as $H_1 \cap H_2 \cong G_2(2)'$. Conversely, suppose that $S_{H_1}$ and $S_{H_2}$ intersect in a subgeometry isomorphic to $H(2)^D$. Then $\Sigma_{H_1} \cap \Sigma_{H_2}$ contains all central involutions that are contained in a certain $G_2(2)'$-subgroup $K_i$ of $H_i \cong J_2$, $i = 1, 2$. Since all these central involutions generate $K_i$, the groups $K_1$ and $K_2$ are equal, say to $K$. As $K$ is a maximal subgroup of both $H_1$ and $H_2$, we have $K = H_1 \cap H_2$, i.e. $H_1$ and $H_2$ are adjacent in the $G_2(4)$-graph.

Therefore, we see that the $G_2(4)$ graph has a symmetric construction using the Hall-Janko suboctagons of the new near octagon $O_1$. It can be easily checked in the computer model that when two such suboctagons do not intersect in a subgeometry isomorphic to $H(2)^D$, they intersect in a point pencil (set of point at distance at most 1 from a fixed point) of suboctagons. And thus we obtain Theorem 6.1.1 for the case of $i = 3$. The remaining cases of $i \in \{0, 1, 2\}$ also follow from similar reasoning, but those results are “well-known” and we skip the details here. Turning our focus to the Suzuki graph, we see that as a consequence of Lemma 6.2.1 the construction given in Theorem 6.1.2 is the geometrical translation of the original construction given by Suzuki. Note that two lines of the lines spread $S_1$ are at distance 1 from each other if and only if the corresponding $2^2$-subgroups of $G_2(4):2$ commute. The only thing left to check is the adjacency between elements of $V(\Delta)$ and $S$, where $\Delta$ is the $G_2(4)$-graph and $S$ is the line spread $S_1$ of $O_1$. From Lemma 5.5.5 we know that every automorphism of $O_1$ which stabilizes a Hall-Janko suboctagon $\mathcal{H}$ must be a conjugation by an element of the $J_2:2$-subgroup corresponding to $\mathcal{H}$. From this it follows that if $x \in S$ and $v \in V(\Delta)$, then a non-trivial element of the subgroup corresponding to $x$ fixes $v$ if and only if the spread line corresponding to $x$ intersects the Hall-Janko suboctagon corresponding to $v$. 

Page 92
6.3. Characterization of the Suzuki Tower

6.3.1. Hall-Janko Near Octagon

For this section let $S'$ be a near octagon of order $(2, 4)$ with a generalized hexagon $S$ isomorphic to $H(2)^D$ isometrically embedded in it. The valuation geometry $V$ of $S$ is described in Tables 2.3 and 2.4. From Table 2.4 it can be seen that the set of valuations of type $A$ and $B$ form a subspace of $V$, and hence we can define a full subgeometry $V_{A,B}$ of $V$ induced by these valuations. In this section we will show that $S'$ is isomorphic to $V_{A,B}$. Since HJ is a near octagon of order $(2, 4)$ with $H(2)^D$ isometrically embedded in it, this will prove Theorem 6.1.4.

**Lemma 6.3.1.** (1) Each point of $S'$ is at distance at most 2 from $S$.

(2) Points at distance 1 from $S$ must be of type $A$, $B$ or $C$.

(3) Points at distance 2 from $S$ must be of type $C$ or $D$.

**Proof.** Since the maximum value of a valuation of $S$ is at least 2 (see Table 2.3) and the diameter of $S'$ is 4, by Lemma 2.2.4 the distance of any point of $S'$ to $S$ is at most 2. This proves (1). Again by Lemma 2.2.4 if a point $x$ of $S'$ lies at distance 2 from $S$, then $f_x$ has maximum value at most 2, implying that $x$ can only be of type $C$ or $D$.

Now, let $x$ be a point of type $D$ at distance 1 from $S$. The five points with $f_x$-value 0 in $S$ must be collinear with $x$ and necessarily be of type $A$ (all points in $S$ are of type $A$). By Theorem 2.3.2 and Table 2.4 this gives rise to five distinct $V$-lines of type ADD through a valuation of type $D$ in the valuation geometry $V$ of $S$, which contradicts the corresponding entry in Table 2.4. 

**Lemma 6.3.2.** Each point of $S'$ at distance 1 from $S$ must be of type $A$ or $B$.

**Proof.** Let $x$ be a point of type $C$ at distance 1 from $S$. We see from Table 2.3 that there is a unique point $x'$ in $S$ collinear with $x$. Again from Table 2.3 we see that there are 22 points with $f_x$-value 1 in $S$, which must necessarily be at distance 2 from $x$. Six of these points are neighbors of $x'$ in $S$ and these are the only ones that have a common neighbor with $x$ that lies inside $S$ (namely $x'$). The remaining 16 points give rise to neighbors of $x$ that lie outside $S$. Since the order of $S'$ is $(2, 4)$ and $x'$ lies in $S$ there are only 9 neighbors of $x$ that lie outside $S$. Therefore, at least one such neighbor $y$ must be collinear with more than one point in $S$. By Lemma 6.3.1 the point $y$ must be of type $A$, $B$ or $C$ and for each of these possibilities we have $|O_{f_y}| = 1$. This is a contradiction.

**Lemma 6.3.3.** If $x$, $y$ are two points of $S'$, not contained in $S$, of type $A$ and $B$ respectively, then $x$ and $y$ cannot be collinear.

**Proof.** Let $x$, $y$ be such points and suppose they are collinear. By Lemma 6.3.1 they must be at distance 1 from $S$. The three valuations induced by the three points on the line $xy$ must be distinct (see Theorem 2.3.2) and therefore, the line $xy$ gives rise to a $V$-line of $S \cong H(2)^D$. From Table 2.4 it follows that the line $xy$ is of type $ABB$. Let $y'$ be the unique neighbor of $y$ in $S$. Then by a similar reasoning the line $y'y$ is also of type $ABB$. But, in the valuation geometry there is a unique line of type $ABB$ through a valuation of type $B$. Therefore, the points $x$ and $y'$ induce the same type $A$ valuation, which shows that $O_{f_x} = \{y'\}$ and hence, $x$ and $y'$ are collinear. This contradicts the fact that $S'$ is a near polygon.
Lemma 6.3.4. If \( x \) is a point of type B in \( S' \), then it has a unique neighbor in \( S \) and all the other neighbors of \( x \) must induce distinct type B valuations of \( S \).

Proof. Let \( x \) be such a point, necessarily at distance 1 from \( S \) by Lemma \[6.3.1\]. By Lemma \[2.2.4\] and Table \[2.3\] it has a unique neighbor, say \( x' \), in \( S \). There are 14 points with \( f_x \)-value 1 in \( S \) and 6 of them are the neighbors of \( x' \). The remaining 8 must give rise to neighbors of \( x \) lying outside \( S \). Let \( y \) be such a neighbor. By Lemmas \[6.3.2\] and \[6.3.3\], \( y \) must be of type B and then by Lemma \[2.2.4\] it cannot lie on the line \( xx' \) (as then \( y \), which is a type B valuation, will have 2 neighbors in \( S \)). Therefore, we get 8 type B neighbors of \( x \) each corresponding to a distinct valuation of \( S \) (since the set \( O_f \) is distinct for each such valuation). The third point on the line \( xx' \) must also be of type B and induce a valuation distinct from all other type B neighbors of \( x \). Since the order of \( S' \) is \((2,4)\), we have accounted for all neighbors of \( x \). \( \square \)

The following is an immediate consequence of Lemma \[6.3.4\]:

Corollary 6.3.5. There are no lines in \( S' \) of type BCC or BDD.

Lemma 6.3.6. There is no point in \( S' \) of type C or D.

Proof. Let \( x \) be such a point, necessarily at distance 2 from \( S \) (see Lemmas \[6.3.1\] and \[6.3.2\]). We treat the two cases separately.

Case 1: Let \( x \) be of type D. By Table \[2.3\] \(|S \cap \Gamma_2(x)| = 5\). Every line through \( x \) that contains a point in \( \Gamma_1(S) \) must be of type ADD by Table \[2.6\], Lemma \[6.3.2\] and Corollary \[6.3.5\]. Since each of these lines has exactly one point which lies in \( \Gamma_1(S) \), and since that point (of type A) has a unique neighbor in \( S \), it must be the case that all five lines through \( x \) are of type ADD. In fact, this also shows that these five lines correspond to five distinct lines in the valuation geometry. But we know from Table \[2.4\] that there are only three lines of type ADD through a point of type D in the valuation geometry, a contradiction.

Case 2: Let \( x \) be of type C. Since \( |O_{f_x}| = 1 \), we have \( O_{f_x} = \Gamma_2(x) \cap S = \{x'\} \) for some \( x' \in S \). Since there are no points of type D (by Case 1) and no lines of type BCC (by Corollary \[6.3.5\]), all lines through \( x \) must be of type ACC or CCC by Table \[2.4\]. Each of the type A neighbors of \( x \) induces the valuation \( f_{x'} \) of \( S \). Therefore, besides the 6 neighbors of \( x' \) in \( S \), every point of \( S \) that has \( f_x \)-value 1 must be at distance 2 from a type C neighbor of \( x \). There are 16 = 22 - 6 points with \( f_x \)-value 1 in \( S \) that are not neighbor of \( x' \). Since there are at most 9 type C neighbors of \( x \), there must be a type C neighbor \( y \) of \( x \) which is at distance 2 from two distinct points of \( S \). This contradicts the fact that \( |O_{f_y}| = 1 \) (\( y \) is a type C point). \( \square \)

By Lemmas \[6.3.1\] and \[6.3.6\] we have:

Corollary 6.3.7. Every point \( x \) of \( S' \) not contained in \( S \) has type A or B, and lies at distance 1 from a unique point of \( S \) (which we will refer to as the projection of \( x \) in \( S \)).

Lemma 6.3.8. Let \( Q \) be a quad of \( S' \) that intersects \( S \) nontrivially. Then \( Q \cap S \) is either a singleton or a line.

Proof. Say \( Q \cap S \) is not a singleton. Since \( Q \cap S \) is a subspace of \( S' \), it suffices to show that there are no two non-collinear points in \( Q \cap S \). Let \( x, y \) be two non-collinear points in \( Q \cap S \). Since \( Q \) is a non-degenerate generalized quadrangle, there are at least two common neighbors of \( x \) and \( y \) in \( Q \). Since points at distance 2 in \( S \cong H(2) P \) have a unique common neighbor and \( Q \cap S \) is a convex subspace, at least one of these common neighbors must lie outside \( S \). This gives rise to a point at distance 1 from \( S \) with two neighbors (\( x \) and \( y \)) in \( S \), which contradicts Corollary \[6.3.7\]. \( \square \)
Lemma 6.3.9. If \( x \) is a point of type \( A \) in \( S' \) which is not contained in \( S \), then there exists a unique \( W(2) \)-quad \( Q \) containing \( x \) and its projection \( x' \) in \( S \). For this quad \( Q \) we have:

(a) \( Q \) intersects \( S \) in a line \( M \).

(b) Let \( M_1 \) and \( M_2 \) be the two lines through \( x' \) in \( S \) other than \( M \). Then the two lines through \( x \) that are not contained in \( Q \) can be labelled \( L_1 \) and \( L_2 \) such that \( L_1, M_1 \) are parallel and at distance 1 from each other, and \( L_2, M_2 \) are parallel and at distance 1 from each other.

Proof. Let \( x \) be a point of type \( A \) outside \( S \) and let \( x' \) be the unique point in \( S \) collinear with \( x \). We have \( f_x = f_{x'} \). Each of the four lines through \( x \) which lie outside \( S \) are of type \( AAA \) by Lemmas 6.3.3 and 6.3.6. From Table 2.4 we see that there are only three distinct lines of type \( AAA \) through a valuation of type \( A \) in the valuation geometry. Therefore, there exists two lines \( K_1, K_2 \) through \( x \) which lie in \( \Gamma_1(S) \) and induce the same set of valuations on \( S \). Let \( \{f_1, f_2, f_3\} \) be this set with \( f_1 = f_x = f_{x'} \). Since all three lines through \( x' \) which lie inside \( S \) correspond to distinct lines of type \( AAA \) in the valuation geometry, at least one of them, say \( M \), must induce the set \( \{f_1, f_2, f_3\} \) of valuations.

Let \( y \neq x' \) be a point on \( M \). Then \( y \) is collinear with a point on \( K_1 \) and a point on \( K_2 \) both of which induce the valuation equal to \( f_y \). Therefore, \( x, y \) are two points at distance 2 in a near polygon with at least three common neighbors. From Theorem 1.3.8 it follows that \( x \) and \( y \) lie in a unique quad \( Q \). By the classification of quads of order \((2, t)\) and Lemma 1.3.13, \( Q \) must be isomorphic to \( W(2) \), the unique generalized quadrangle of order \((2, 2)\). From Lemma 6.3.8 it follows that \( Q \cap S = M \) and hence, for each point on \( M \), the two lines through it going out of \( S \) are contained in \( Q \). Hence none of the points on \( M \) can be contained in a \( W(2) \)-quad other than \( Q \).

Now let \( L \) be a line through \( x \) not contained in \( Q \). \( L \) necessarily induces a set of valuations other then \( \{f_1, f_2, f_3\} \). There are only two other possibilities and both of them are induced by lines through \( x' \) contained in \( S \), but not in \( Q \). Therefore there must be a line \( L' \) through \( x' \) inducing the same set of valuations as \( L \). The correspondence \( L \mapsto L' \) between the set of lines through \( x \) not contained in \( Q \) and the set of lines through \( x' \) in \( S \) distinct from \( M \) is a bijection as otherwise there would exist another \( W(2) \)-quad through the line \( xx' \) but we have already proved that there is a unique such quad.

Lemma 6.3.10. There is no point in \( S' \) of type \( A \) outside \( S \).

Proof. Let \( x \) be a point of type \( A \) outside \( S \). By Lemma 6.3.9 it lies in a unique \( W(2) \)-quad \( Q \) which intersects \( S \) in a line \( L \). By Lemma 6.3.3 and Corollary 6.3.7, all points of \( Q \setminus L \) have type \( A \). Let \( x' \) be the projection of \( x \) in \( S \) and \( y' \) a neighbor of \( x' \) in \( S \) lying on a line through \( x' \) other than \( L \). By Lemma 6.3.9, there exists a unique neighbor \( y \) of \( y' \) outside \( S \) and collinear with \( x \). Again by Lemma 6.3.3 and Corollary 6.3.7, the point \( y \) has type \( A \). So, by Lemma 6.3.9 there exists a unique \( W(2) \)-quad \( S \) containing \( y \) and \( y' \). The \( W(2) \)-quads \( Q \) and \( S \) are disjoint.

Suppose \( p \) is a neighbor of \( x' \) contained in \( Q \setminus L \). As \( p \) has type \( A \), there exists by Lemma 6.3.9 a unique line through \( p \) disjoint from \( S \) that is parallel and at distance 1 from the line \( xx' \), implying that there is a common neighbor of \( p \) and \( y' \) in \( S \setminus \{p\} \). This implies that we can label the two lines of \( Q \) through \( x' \) distinct from \( L = Q \cap S \) by \( T_1 \) and \( T_2 \) and the two lines of \( S \) through \( y' \) distinct from \( S \cap S \) by \( U_1 \) and \( U_2 \) such that \( T_1, U_1 \),
are parallel and at distance 1 from each other, and $T_2, U_2$ are parallel and at distance 1 from each other.

Now, consider a point $z$ in $S$ which is not collinear with $y'$. If $z$ is at distance 1 from $Q$ (necessarily from a point of type $A$ of $Q \setminus L$), then by Lemma 6.3.9 its projection $z' \in S \cap S$ is collinear with a point on the line $L$ in $S$, contradicting the fact that $S$ is a generalized hexagon. So $z$ (as well as every point of $S$ non-collinear with $y'$) must be at distance at least 2 from $Q$. The two lines of $S$ through $y'$ distinct from $S \cap S$ are parallel and at distance 1 from a line of $Q$. So, taking the projection of $z$ on these two lines, we see that there are two points in $Q$ at distance 2 from $z$. By Theorem 2.2.2, the point $z$ induces a classical or an ovoidal valuation of $Q$. Since there are two points in $Q$ at distance 2 from $z$, the point $z$ must induce an ovoidal valuation of $Q$. Since there are five points in an ovoid in $Q$ ($\cong W(2)$), each of the five lines through $z$ must contain a (necessarily unique) point at distance 1 from $Q$. Thus the projection of $z$ on $S$, $z'$, must be collinear with a point in $Q$. Now, all the lines through $z'$ are either in $S$ or in $S$. Since $S$ and $Q$ are disjoint and $S$ is a generalized hexagon, we have a contradiction.

Therefore, $S'$ has the following description:

- each point of $S'$ is at distance at most 1 from $S$;
- each point of $S'$ that lies in $S$ induces a valuation of type $A$, and
- each point of $S'$ that does not lie in $S$ induces a valuation of type $B$.

Obviously, distinct points of $S'$ induce distinct type $A$ valuations since their zero sets are distinct. To prove that $S'$ is isomorphic to $V_{A,B}$, we first show that no two points in $S'$ can induce the same type $B$ valuation of $S$, which will give us a bijection between the point sets of these geometries.

**Lemma 6.3.11.** If $g_1$ and $g_2$ are two distinct valuations of type $B$ collinear to each other in the valuation geometry of $S$, then we have $|\{x \in S' \setminus S \mid f_x = g_1\}| = |\{x \in S' \setminus S \mid f_x = g_2\}|$

**Proof.** Let $g_1$, $g_2$ be two such valuations of type $B$. Say a point $y$ in $S'$ induces the valuation $g_1$ of $S$. If $g_1$ and $g_2$ lie on $V$-line of type $ABB$, then the third point on the line joining $y$ and the unique neighbor of $y$ that lies in $S$ induces the valuation $g_2$, giving us a bijection between $\{x \in S' \setminus S \mid f_x = g_1\}$ and $\{x \in S' \setminus S \mid f_x = g_2\}$. So, say $g_1$ and $g_2$ lie on $V$-line of type $BBB$. Then by Lemma 6.3.4 we know that each of the four lines through $y$ which do not intersect $S$ must induce distinct $V$-lines of type $BBB$. But we know from Table 2.3 that there are exactly four such $V$-lines containing $g_1$, and hence $g_2$ is contained in exactly one of them. Therefore, there must be precisely one neighbor of $y$ in $S' \setminus S$ which induces the valuation $g_2$. This gives a bijection between $\{x \in S' \setminus S \mid f_x = g_1\}$ and $\{x \in S' \setminus S \mid f_x = g_2\}$. \hfill $\Box$

**Lemma 6.3.12.** The subgeometry of $V$ defined on the type $B$ valuations by the lines of type $ABB$ and $BBB$ is connected.

**Proof.** This is easily checked via computations in the computer model of the valuation geometry of $H(2)^D$ obtained using the code given in Chapter 3. \hfill $\Box$

**Corollary 6.3.13.** For each type $B$ valuation $f$ of $S$, there exists exactly one point $x \in S'$ with $f_x = f$. 
Proof. Since each point of $S$ is collinear with precisely four points of $S' \setminus S$, and each point of $S' \setminus S$ has a unique neighbor in $S$, we have $|S' \setminus S| = 4|S| = 252$. By Lemmas 6.3.11 and 6.3.12 we know that for every pair of type $B$ valuations there exist equally many points in $S'$ which induce those valuations. But from Table [2.3] we can see that there are exactly 252 valuations of type $B$. Therefore each type $B$ valuation is induced exactly once.

Now we can prove that $S'$ is isomorphic to $V_{A,B}$ as follows. Map every point $x$ of $S'$ to the valuation of type $T \in \{A, B\}$ that it induces. Since no two points of $S'$ induce the same valuation (see Corollary 6.3.13), for every line $L = \{x, y, z\}$ of $S'$ the triple $\{f_x, f_y, f_z\}$ is a $V$-line. Map every line of $S'$ to this corresponding line of $V_{A,B}$. Since $S'$ and $V_{A,B}$ have the same number of points and the same order $(2, 4)$, the above maps between the point and line sets of $S'$ and $V_{A,B}$ are bijections and it defines an isomorphism between the two geometries by Theorem 2.3.2. Thus, every near polygon of order $(2, 4)$ that contains an isometrically embedded generalized hexagon $S$ isomorphic to $H(2)^D$ must be isomorphic to $V_{A,B}$, which proves Theorem 6.1.4.

### 6.3.2. $G_2(4)$ Near Octagon

For this section let $S'$ be a near octagon with three points on each line containing a suboctagon $S$ isomorphic to $HJ$ isometrically embedded in it. The valuation geometry $V$ of $S \cong HJ$ is given in Tables [2.7] and [2.8]. The main purpose of this section is to show that if $S'$ has order $(2, 10)$, then $S$ is isomorphic to the $G_2(4)$ near octagon constructed in Chapter 5. We use the same approach as in Section 6.3.1 of showing that if $S'$ has order $(2, 10)$, then it consists of points of type $A$, $B$ or $C$ and lines of type $AAA$, $ABB$, $ACC$, $BBC$ or $CCC$, with each type occurring exactly once, which proves that up-to isomorphism there is at most one near octagon of order $(2, 10)$ containing $HJ$ as an isometrically embedded subgeometry. Since in Chapter 5 we showed that $HJ$ is indeed an isometrically embedded subgeometry of the $G_2(4)$ near octagon (see Lemma 5.4.9), this will prove the result. First we derive some general results that are true for any near octagon $S'$ with three points on each line that contains $S$ as a full isometrically embedded subgeometry and later restrict ourselves to the case when $S'$ has order $(2, 10)$. The following four lemmas are proved using the computer model of the valuation geometry of $HJ$ constructed using the methods of Chapter 3.

**Lemma 6.3.14.** Let $f$ be a valuation of type $C$ and let $g \neq f$ and $h \neq f$ be valuations of type $B$ or $C$ lying on distinct $V$-lines through $f$. Then $g$ and $h$ are non-collinear.

**Lemma 6.3.15.** Let $f$ be a valuation of type $B$ and let $x \in S$ be the unique point in $O_f$. Then the map $\{f, g, h\} \rightarrow O_f \cup O_g \cup O_h$ is a bijection between the set of five $V$-lines of type $BBB$ through $f$ and the set of five lines of $H$ through $x$.

**Lemma 6.3.16.** Let $f$ be a valuation of type $C$. Then there is a unique $V$-line $\{f, g, h\}$ of type $CCC$ through $f$ such that $O_f \cup O_g \cup O_h$ is a line of $HJ$. For every other $V$-line $\{f, g', h'\}$ of type $CCC$ through $f$, the set $O_f \cup O_g' \cup O_{h'}$ is a set of three pairwise non-collinear points.

A $V$-line $\{f, g, h\}$ of type $CCC$ will be called special if $O_f \cup O_g \cup O_h$ is a line of $HJ$. If that is not the case, then $\{f, g, h\}$ will be called an ordinary $V$-line. This concept of special and ordinary is then extended to the lines of $S'$ that induce $V$-lines of type $CCC$. 

Lemma 6.3.17. The subgeometry of $\mathcal{V}$ defined on the type $C$ valuations by the lines of type $ACC$ and the ordinary lines of type $CCC$ is connected.

Remark. Lemmas 6.3.14 and 6.3.16 could alternatively be verified by a geometric reasoning inside the $G_2(4)$ near octagon, keeping in mind the construction of this near octagon using the valuation geometry of $\mathcal{HJ}$ (see Proposition 5.4.15).

Lemma 6.3.18. Every point of $S'$ is at distance at most 2 from $S$. Points of $S$ are of type $A$, points at distance 1 from $S$ are of type $B$ or $C$ and those at distance 2 are of type $D$ or $E$.

Proof. Since $S$ is isometrically embedded in $S'$, all points of $S$ induce type $A$ valuations. From Lemma 2.2.4 and the column $M_f$ of Table 2.7, we see that the points in $\Gamma_1(S)$ cannot be of type $A$, but the points in $\Gamma_2(S)$ must be of type $D$ or $E$. If $x \in \Gamma_1(S)$, then there exists a line through $x$ that intersects $S$, which must necessarily be of type $ABB$ or $ACC$ by Table 2.8, implying that $x$ has type $B$ or $C$.

Corollary 6.3.19. Every point of $S'$ at distance 1 from $S$ is collinear with a unique point of $S$.

Proof. Such points are of type $B$ or $C$ and valuations of type $B$ and $C$ have exactly one point of value 0.

Lemma 6.3.20. There are no points of type $E$ in $S'$.

Proof. Let $x$ be a type $E$ point of $S'$. By Lemma 6.3.18, $x$ must be at distance 2 from $S$. Let $y$ be a neighbor of $x$ which lies at distance 1 from $S$. Then $x$ has type $B$ or $C$ by Lemma 6.3.18. Since the valuations $f_x$ and $f_y$ are not equal, the line $xy$ gives rise to a $\mathcal{V}$-line in the valuation geometry of $\mathcal{HJ}$ (see Theorem 2.3.2). But, by Table 2.8 there are no $\mathcal{V}$-lines with both type $E$ and type $T$ points on it, for $T \in \{B, C\}$.

Let $x$ be a point of $S'$ at distance 1 from $S$ which by Lemma 6.3.18 is of type $B$ or $C$. We will call the unique point of $S$ collinear with $x$ (see Corollary 6.3.19) the projection of $x$, and denote it by $\pi(x)$. From now onward we implicitly use the fact that points at distance 1 from $S$ are of type $B$ or $C$. For a line $L = \{x, y, z\}$ contained in $\Gamma_1(S)$ we define the projection $\pi(L)$ of $L$ to be the set $\{\pi(x), \pi(y), \pi(z)\}$ of points of $S$. Since $S'$ is a near polygon, $\pi(L)$ and $L$ have the same size for every line $L$ in $\Gamma_1(S)$. But, this projection may or may not be a line of $S$.

Lemma 6.3.21. Let $x$ be a type $B$ point of $S'$ and let $y$ be a point on a line through $x$ which does not intersect $S$. Then $y$ is at distance 1 from $S$ and the projections $\pi(x)$ and $\pi(y)$ are collinear.

Proof. The point $y$ must be of type $B$ or $C$ since there are no $\mathcal{V}$-lines containing both type $B$ and type $T$ points for $T \in \{D, E\}$ (see Table 2.8) and hence at distance 1 from $S$ by Lemma 6.3.18. The projections $\pi(x)$ and $\pi(y)$ have $f_x$-values 0 and 1, respectively. Since $f_x$ is of type $B$, there are exactly ten points of $S$ that have $f_x$-value 1 (see Table 2.7). Clearly, every point in $S$ at distance 1 from $\pi(x)$ has $f_x$-value 1. Since $S$ has order (2, 4), there are precisely ten such points and hence $\pi(y)$ must be one of them.

Corollary 6.3.22. If $x$ is a point of type $B$ in $S'$, then every line through $x$ that does not intersect $S$ is parallel to and at distance 1 from a unique line of $S$.

Lemma 6.3.23. Every type $B$ point $x$ of $S'$ is incident with a line of type $BBC$. 

Page 98
Proof. Let \( x \) be a point of type \( B \). Then every point of \( S \) at distance 1 from \( \pi(x) \) has \( f_x \)-value 1. Since \( O_{f_x} = \{ \pi(x) \} \) every point of \( S \) at distance 2 from \( \pi(x) \) should have \( f_x \)-value 2, and since \( S \) is a regular near octagon with parameters \((2, 4; 0, 3)\), there are 80 such points. By Table 2.7 there are 112 points of \( S \) with \( f_x \)-value 2. Let \( y \) be one of the other 112 – 80 = 32 points with \( f_x \)-value 2 at distance at least 3 from \( \pi(x) \). Since \( f_x(y) = 2 \), we have \( d(x, y) = 3 \). Let \( x, u, v, y \) be a path of length 3 connecting \( x \) and \( y \). By Lemmas 6.3.18 and 6.3.21 the point \( u \) has type \( A \), \( B \) or \( C \). We will show that \( u \) is of type \( C \), hence proving that the line \( xu \) is of type \( BBC \).

If \( u \) is of type \( A \), then \( u = \pi(x) \), which would be in contradiction with \( d(\pi(x), y) > 2 \). Suppose \( u \) is of type \( B \), and hence at distance 1 from \( S \). From Corollary 6.3.22 we see that \( \pi(u) \) and \( \pi(x) \) are collinear (or equal). We cannot have \( v = \pi(u) \) as that would imply that \( d(\pi(x), y) \leq 2 \). Therefore, \( v \) lies outside \( S \) and \( y \) must be equal to \( \pi(v) \). Again by Corollary 6.3.22 \( y = \pi(v) \) and \( \pi(u) \) must be collinear (or equal), which contradicts the fact that \( d(\pi(x), y) > 2 \). So, \( u \) is of type \( C \).

Corollary 6.3.24. There exist type \( C \) points in \( S' \).

Proof. As there exist points at distance 1 from \( S \), there exist points of type \( B \) or \( C \). The existence of type \( B \) points implies the existence of type \( C \) points by Lemma 6.3.23.

Lemma 6.3.25. Let \( x \) be a point of \( S' \) of type \( C \) and let \( L_1, L_2 \) be two distinct lines of type \( CCC \) through \( x \). Then the \( V \)-lines corresponding to \( L_1 \) and \( L_2 \) must be distinct.

Proof. Let \( L_1 = \{x, y, z\} \) and \( L_2 = \{x, y', z'\} \). Assume that they correspond to the same \( V \)-line so that \( f_y = f_y' \) and \( f_z = f_z' \). Let \( u := \pi(z) = \pi(z') \). Since \( xuzz' \) is a quadrangle, the point \( y \) must be collinear with the third point on the line \( uz' \), call it \( v \). Therefore, the valuations \( f_v \) and \( f_y = f_y' \) are collinear in \( V \). The collinearity of \( f_v \) and \( f_y' \) in \( V \) contradicts Lemma 6.3.14 by taking \( f = f_{x'}, g = f_{y'} \) and \( h = f_v \).

On the valuations of type \( C \) we can define a subgeometry of \( V \) induced by the lines of type \( ACC \) and the ordinary lines of type \( CCC \). Let this subgeometry be denoted by \( V_C \) and its collinearity graph by \( \Gamma_1 \). Similarly, we can define a subgeometry \( S'_{C'} \) of \( S' \) by taking the points of type \( C \) and the lines that correspond to lines of \( V_C \). Let \( \Gamma_2 \) be the collinearity graph of \( S'_{C'} \). Since type \( C \) points exist in \( S' \), the graph \( \Gamma_2 \) is nonempty.

Lemma 6.3.26. The graph \( \Gamma_2 \) is a cover of the graph \( \Gamma_1 \) by the map \( x \mapsto f_{x} \).

Proof. Let \( x \) be a point of type \( C \) in \( S' \). There are 16 points of \( f_x \)-value 1 that are not collinear with \( \pi(x) \) (see Table 2.7). Denote this set of 16 points by \( U \). If \( u \in U \), then \( d(x, u) = 2 \). Denote by \( v \) a common neighbor of \( x \) and \( u \). Since \( v \neq \pi(x), v \notin S \) and \( u = \pi(v) \), the point \( v \) cannot be contained on the line \( xu(x), \) and so \( xv \) is a line disjoint from \( S \). Since \( \pi(x) \) and \( \pi(v) = u \) are not collinear, Lemma 6.3.21 implies that \( v \) has type \( C \) and hence that \( xv \) is a (necessarily ordinary) line of type \( CCC \).

By Lemmas 6.3.16, 6.3.25 and Table 2.8 there are at most 8 ordinary lines of type \( CCC \) through \( x \), each of which determines two points of the set \( U \). Since \(|U| = 16 \), it follows that there are precisely 8 ordinary lines of type \( CCC \) through \( x \) and they correspond bijectively to the 8 ordinary \( V \)-lines of type \( CCC \) through \( f_x \). This proves that the map \( x \mapsto f_{x} \) is a local isomorphism between \( \Gamma_2 \) and \( \Gamma_1 \). The fact that this map is surjective now follows from the connectedness of \( \Gamma_1 \), see Lemma 6.3.17.
Corollary 6.3.27. If \( \Gamma_2 \) is an \( i \)-cover of \( \Gamma_1 \) for some \( i \geq 1 \), then each valuation of type \( C \) is induced by precisely \( i \) type \( C \) points of \( S' \). As a consequence, through each point of \( S \), there are precisely \( 5i \) lines of type \( ACC \).

Proof. By Table 2.8 there are precisely 5 \( V \)-lines of type \( ACC \) through a given valuation of type \( A \). Since each type \( C \) valuation occurs exactly \( i \) times, we have \( 5i \) type \( ACC \) lines in \( S' \) through a given point of \( S \). 

Remark. All results in this section so far are valid for a general near octagon of order \((2, t)\) that contains an isometrically embedded sub near octagon isomorphic to \( HJ \). In the following lemma, we need the fact that \( S' \) has order \((2, 10)\).

Lemma 6.3.28. If \( S' \) is of order \((2, 10)\), then each valuation of type \( T \in \{B, C\} \) is induced exactly once by a point of \( S' \).

Proof. Let \( S' \) be of order \((2, 10)\) and let \( x \) be an arbitrary point of \( S \). Then there are exactly \( 11 - 5 = 6 \) lines through \( x \) that are not contained in \( S \), each of which has type \( ACC \) or \( ABB \). Since type \( C \) points exist by Corollary 6.3.24 \[6.3.27\] it follows from Corollary 6.3.24 \[6.3.27\] that there are precisely 5 lines of type \( ACC \) through \( x \) in \( S' \), and hence the graph \( \Gamma_2 \) is a 1-cover of \( \Gamma_1 \). Now the 6-th line through \( x \) which is not contained in \( S \) must be of type \( ABB \). Therefore, through every point of \( S \) there are 5 lines of type \( ACC \) and a unique line of type \( ABB \). This shows that for every valuation \( f \) of type \( B \), we can find the unique point of \( S' \) that induces \( f \) by first getting the point \( y \) of \( S \) that induces the type \( A \) valuation on the unique \( V \)-line of type \( ABB \) through \( f \) (see Table 2.8), and then picking the point on the unique line of type \( ABB \) through \( x \) in \( S' \) that induces the valuation \( f \). 

For the rest of this section assume that \( S' \) has order \((2, 10)\). From Lemma 6.3.28 \[6.3.28\] we know that both type \( B \) and type \( C \) points exist in \( S' \) and each type \( B \) or type \( C \) valuation of \( S \) is induced by a unique point of \( S' \). Let \( x \) be a point of type \( B \) in \( S' \) and let \( L_x \) be the unique line joining \( x \) and \( \pi(x) \). From Corollary 6.3.22 \[6.3.22\] it follows that every other line through \( x \) gives rise to a quad in \( S' \) that intersects \( S \) and contains \( L_x \).

Lemma 6.3.29. Let \( Q \) be a quad of \( S' \) that intersects \( S \) nontrivially. Then \( Q \cap S \) is either a singleton or a line.

Proof. The proof is similar to that of Lemma 6.3.8 \[6.3.8\].

Lemma 6.3.30. Let \( Q \) be a quad of \( S' \) that is not a grid and that intersects \( S \) in a line \( L \). Then there must exist points of type \( B \) and points of type \( C \) in \( Q \setminus L \).

Proof. For the sake of contradiction assume that all points of \( Q \setminus L \) are of a fixed type \( T \in \{B, C\} \). Let \( x \) be a point of \( L \). Since \( Q \) is not a grid, there exist two lines \( L_1 = \{x, y, z\} \) and \( L_2 = \{x, y', z'\} \) through \( x \) with \( y, y', z, z' \in Q \setminus L \). Let \( w \) be a common neighbor of \( z \) and \( z' \) in \( Q \) which is different from \( x \). Then \( w \in Q \setminus L \). From Lemma 6.3.28 \[6.3.28\] it follows that the lines \( wz \) and \( wz' \) correspond to distinct \( V \)-lines, which are of type \( TTT \) by our assumption. Also note that \( \pi(wz) = \pi(wz') = L \). This contradicts Lemma 6.3.15 \[6.3.15\] for \( T = B \) and Lemma 6.3.16 \[6.3.16\] for \( T = C \). 

Lemma 6.3.31. There are no \( Q(5, 2) \)-quads in \( S' \) that meet \( S \) in a line.

Proof. Let \( Q \) be a \( Q(5, 2) \)-quad that meets \( S \) in a line \( L \). By Lemma 6.3.30 \[6.3.30\] there is a point \( x \) of type \( C \) in \( Q \). There is a unique line through \( x \) that intersects \( S \) in \( L \), and hence lies in \( Q \). Every other line through \( x \) which is contained in \( Q \) projects to \( L \). By Lemmas
there is at most one line of type $CCC$ through $x$ in $Q$. From Table 2.8 and Lemma 6.3.28 it follows that there is at most one line of type $BBC$ through $x$ in $Q$. Therefore, in total we have at most three lines through $x$ in $Q$ which contradicts the fact that the order of a $Q(5,2)$-quad is $(2,4)$.  

**Lemma 6.3.32.** Let $x$ be a point of type $B$ in $S'$. Then $x$ cannot be contained in two lines $L_1$, $L_2$ such that $L_1$ has type $BBB$, $L_2$ has type $BBC$ and $\pi(L_1) = \pi(L_2)$.

*Proof.* Let $L_1 = \{x, y, z\}$ and $L_2 = \{x, y', z'\}$ be two such lines, such that $\pi(y) = \pi(y')$ and $\pi(z) = \pi(z')$. Say $L_1$ is of type $BBB$ and $L_2$ of type $BBC$. Without loss of generality assume that $z$ is of type $C$. Then the lines $y\pi(y)$ and $y'\pi(y')$ are of type $ABB$. By Table 2.8 there is only one $V$-line of type $ABB$ projecting to a valuation of type $A$, and hence $f_y$ is equal to $f_y'$ or $f_{y''}$ where $y''$ is the third point (of type $B$) on the line $y'\pi(y')$. This contradicts Lemma 6.3.28. 

**Lemma 6.3.33.** Let $x$ be a point of type $B$ in $S'$. Then

1. $x$ is incident with a unique line of type $ABB$ and ten lines of type $BBC$;
2. these ten type $BBC$ lines through $x$ correspond bijectively to the ten $BBC$ lines of the valuation geometry $V$ through $f_x$, and they are partitioned into pairs by five $W(2)$-quads passing through the line of type $ABB$ through $x$.

*Proof.* There is a unique line through $x$ that intersects $S$, namely the line joining $x$ and $\pi(x)$. Every other line through $x$ is of type $BBB$ or $BBC$ which is entirely contained in $\Gamma_1(S)$ and is parallel to a line through $\pi(x)$ in $S$ (see Corollary 6.3.22). Let $S$ denote the set of these other lines through $x$. By Lemma 6.3.28 distinct lines in $S$ correspond to distinct $V$-lines. Let there be $i$ lines of type $BBB$ in $S$, with $i \leq 5$ by Table 2.8. Since we cannot have two lines of type $BBC$ and $BBB$ in $S$ projecting to the same line of $S$ by Lemma 6.3.32 and since there are no $Q(5,2)$-quads by Lemma 6.3.31, there are at most $2(5 - i)$ lines of type $BBC$ in $S$, and hence in total at most $2(5 - i) + i + 1 = 11 - i$ lines through $x$. Therefore, we have $i = 0$ and each of the 5 lines of $S$ through $\pi(x)$ is parallel to exactly 2 lines of $S$. This gives rise to 5 $W(2)$-quads through the line $x\pi(x)$, that partition $S$ into pairs.

We are now ready to prove Theorem 6.1.5. From Lemma 6.3.33 it follows that there are no lines of type $BBB$ in $S'$. Since each of the type $A$, $B$ and $C$ valuations is induced by a unique point of $S'$ and each $V$-line of type $AAA$, $ABB$ and $ACC$ is induced by a unique line of $S'$, it suffices to show that also every $V$-line of type $BBC$ and $CCC$ is induced by a unique line of $S'$, and that type $D$ points do not exist in $S'$ (we have already proved in Lemma 6.3.20 that type $E$ points do not exist).

Let $\{f, g, h\}$ be a $V$-line of type $BBC$ where $f$ is of type $B$. Let $x$ be the unique point in $S'$ with $f_x = f$. By Lemma 6.3.33 there exists a line $L = \{x, y, z\}$ such that $f_y = g$ and $f_z = h$. This shows that each $V$-line of type $BBC$ is induced by a necessarily unique line of $S'$.

Now, let $x$ be a point of type $C$. Since $\Gamma_2$ is a 1-cover of $\Gamma_1$, there exist eight ordinary lines of type $CCC$ through $x$ that bijectively correspond to the eight ordinary $V$-lines of type $CCC$ through $f_x$. By Table 2.8 there exists a unique $V$-line of type $BBC$ through $f_x$, implying that in $S'$ there is a unique line $L$ of type $BBC$ through $x$. By Lemma 6.3.33 $L$ lies in a $W(2)$-quad $Q$, which must also contain the unique line of type $ACC$ through $x$. The third line in $Q$ through $x$ must be a special line of type $CCC$ as there is a unique
type \(BBC\) line through \(x\) and none of the ordinary type \(CCC\) lines through \(x\) projects to a line of \(S\). Therefore, the unique special \(V\)-line of type \(CCC\) through \(f_x\) is induced by a line of \(S'\). Since we have accounted for all 11 lines through a point of type \(C\), there cannot be any lines of type \(CDD\), and hence there cannot be any points of type \(D\) in \(S'\). This completes the proof as we have shown that \(S'\) is isomorphic to the \(G_2(4)\) near octagon.
Part II.

Polynomial Method
7. Introduction

The polynomial method is an umbrella term for different techniques involving polynomials which have been used to solve several problems in finite geometry, discrete geometry, extremal combinatorics and additive number theory. One of the general philosophies behind this method is to associate a set of polynomials (possibly a single polynomial), to a combinatorial object that we want to study, and then use some properties of these polynomials to describe the combinatorial object. For a concrete example, let us go through Koornwinder’s proof of the absolute bound on equiangular lines.

A set of lines in the Euclidean space \( \mathbb{R}^n \) through the origin (or any other fixed point) is called equiangular if the angle between every pair of distinct lines in the set is the same. For example, joining the opposite vertices of a regular hexagon in the plane \( \mathbb{R}^2 \), we get three equiangular lines.

At most how many equiangular lines can there be in \( \mathbb{R}^n \)?

This question was addressed by Gerzon (as reported by Lemmens and Seidel in [102]), who proved that there are at most \( \binom{n+1}{2} \) equiangular lines in \( \mathbb{R}^n \). Thus in particular, the regular hexagon example gives us the maximum possible equiangular lines in \( \mathbb{R}^2 \). But in general this bound is not sharp. In 1976, Koornwinder gave an “almost trivial proof” [100] of Gerzon’s bound by giving a bijective correspondence between the set of equiangular lines in \( \mathbb{R}^n \) and a linearly independent set of polynomials lying in an \( \binom{n+1}{2} \)-dimensional vector space. This correspondence is as follows. Let \( L_1, \ldots, L_k \) be \( k \) equiangular lines in \( \mathbb{R}^n \) and let \( u_1, \ldots, u_k \) be unit vectors on these lines, chosen arbitrarily. Then we have \( \langle u_i, u_j \rangle^2 = \alpha \) for \( i \neq j \) where \( \alpha \) is a fixed real number in the interval \([0, 1)\). For \( i \in \{1, \ldots, k\} \), define \( f_i \in \mathbb{R}[t_1, \ldots, t_n] \) by \( f_i(t_1, \ldots, t_n) = (\langle u_i, (t_1, \ldots, t_n) \rangle)^2 - \alpha^2 (t_1^2 + \cdots + t_n^2) \). Now since \( f_i(u_j) = 0 \) for \( i \neq j \) and \( f_i(u_i) = 1 - \alpha^2 \neq 0 \) for all \( i \), it is easy to see that \( f_1, \ldots, f_k \) are linearly independent polynomials in the vector space \( \mathbb{R}[t_1, \ldots, t_n] \). As these polynomials lie in the \( \binom{n+1}{2} \)-dimensional subspace of \( \mathbb{R}[t_1, \ldots, t_n] \) spanned by the monomial set \( \{t_i t_j \}_{1 \leq i \leq j \leq n} \), we get \( k \leq \binom{n+1}{2} \).

The argument above can also be seen as an example of the linear algebra method in combinatorics, which has been discussed in much detail in the influential (unfinished) manuscript of Babai and Frankl [8], and more recently in the beautiful book by Matoušek [108].

Another important way of using polynomials is to capture the combinatorial object via zeros of polynomials (or in general, algebraic varieties). One of the earliest examples here is the determination of the minimum size of an affine blocking set by Jamison in 1977 [93]. The problem is to find the minimum number of points required to “block” every hyperplane of the affine space \( \mathbb{F}_q^n \). Clearly \( n(q-1) + 1 \) points suffice (by taking

\[1\text{In fact, this is one of the earliest papers that played an important role in the development of polynomial method.}\]
Introduction

all points that lie on one of the \( n \) axes), but can we do better? Jamison proved that we cannot, and his polynomial method proof can be sketched as follows: (a) first consider the dual problem, which is equivalent to finding the minimum number of hyperplanes required to cover all points of \( \mathbb{F}_q^n \) except the origin, (b) then identify \( \mathbb{F}_q^n \) with the finite field \( \mathbb{F}_{q^m} \), (c) finally associate each hyperplane with the minimal polynomial over \( \mathbb{F}_{q^m} \) that vanishes on the hyperplane to show (using the theory of linearized polynomials [103, Chapter 3]) that if the number of hyperplanes is less than \( n(q - 1) + 1 \), then the polynomial \( t^{q^n - 1} - 1 = \prod_{\alpha \in \mathbb{F}_{q^n}^*} (t - \alpha) \), does not divide the product of these polynomials corresponding to the hyperplanes. This technique of using polynomials over finite fields to solve finite geometrical problems came to be known as the “Jamison method” and it saw several applications (see for example, the surveys [25] and [39]).

Brouwer and Schrijver gave another proof of Jamison’s theorem in [37] where they also started by considering the dual problem of hyperplane coverings but then proceeded by a much simpler argument involving multivariate polynomials over finite fields. Their approach was in fact quite similar to Chevalley’s proof of the famous Chevalley-Warning theorem [47] using reduced polynomials. We will see in Chapters 8 and 9 how both of these results are linked together by the notion of grid reduction, and in particular by the Lemma that a polynomial \( \mathbb{F}_q[t_1, \ldots, t_n] \) which vanishes on all points of \( \mathbb{F}_q^n \) except one must have degree at least \( n(q - 1) \). The Chevalley-Warning theorem, which is a statement on the zero set of a collection of polynomials over a finite field, has also found several applications in combinatorics. Alon, Friedland and Kalai used it to prove that every 4-regular graph plus an edge contains a 3-regular subgraph [2]. Later, Bailey and Richter [9] used the Chevalley-Warning theorem to give a new proof of the famous Erdős-Ginzburg-Ziv theorem in additive number theory [79]. Recently, Clark, Forrow and Schmitt [51] have shown that the Chevalley-Warning theorem and its combinatorial applications can be derived, and further generalized, using a result of Alon and Füredi from 1993 [3, Theorem 5]. We will devote Chapter 9 to this Alon-Füredi Theorem, where we generalize the result and give a new simple proof. We also show how this result is linked to several other topics like coding theory, finite geometry and polynomial identity testing.

An important tool in the polynomial method involving zeros of polynomials is a result called Combinatorial Nullstellensatz [1], which was developed by Alon and his collaborators [4,5]. This powerful tool and its generalizations have been used extensively to solve several problems in additive number theory (see [134, Chapter 9] for a survey) and more recently in some other areas as well [95,96]. In [49], Clark revisited Alon’s Combinatorial Nullstellensatz and showed how its proof can be seen as a “restricted variable analogue” of Chevalley’s proof of the Chevalley-Warning Theorem. He further generalized this result to commutative rings (adding certain extra conditions) and made it clear how many of the ideas involved are related to the notion of grid reduction. In [13], Ball and Serra introduced a related result which they called Punctured Combinatorial Nullstellensatz. This result was proved using Alon’s Combinatorial Nullstellensatz, and it has several combinatorial applications of its own. We will give another proof of this result in Chapter 8 by directly using the notion of grid reduction, and then use this result to prove a new generalization of the Chevalley-Warning theorem which we call the Punctured Chevalley-Warning Theorem. In fact, this result generalizes Brink’s Restricted Variable Chevalley-Warning theorem [29].

\(^2\)Note that we can find a polynomial of degree \( q \) which vanishes on all points, and therefore this is a big jump!
In recent years, there has been a lot of interest in the polynomial method as a result of Dvir’s two-page proof of the finite field Kakeya problem which involved an easy polynomial argument, and the developments that followed. Many experts worked on the finite field Kakeya problem using different techniques involving algebraic geometry and Fourier analysis, but made only partial progress towards a solution to this problem. And thus it was a great surprise to the mathematical community that such an easy polynomial argument could resolve this famous open problem. Ideas originating from Dvir’s work have lead to several important advancements in mathematics, including the breakthrough in the famous Erdős distinct distances problem by Guth and Katz. It is interesting to note that Dvir’s polynomial technique is quite different from the techniques we have mentioned so far in this introduction as it involved polynomial interpolation instead of constructing explicit polynomials. For more details on this, we recommend the surveys by Dvir and Tao, and the recent book by Guth. Another example where a combinatorial problem is solved using polynomial interpolation, combined with a geometric argument, is Segre’s classical theorem on ovals in finite projective planes. Interestingly, the so-called “lemma of tangents” from was used in combination with the Jamison/Brouwer-Schrijver bound on affine blocking sets by Blokhuis and Korchmáros to solve the Kakeya problem in 2 dimensions. Segre’s result (and his lemma of tangents) has been generalized further to higher dimensional finite projective spaces by Ball. For more on polynomial method in finite geometry, see the survey by Ball.

**Notation**

We will be using the following notation in Chapters 8 and 9. For us rings will always be commutative with a multiplicative identity denoted by 1. $R$ denotes an arbitrary ring, and $F$ an arbitrary field. For an $n$-variable polynomial $f \in R[t_1, \ldots, t_n]$ we let $\deg f$ denote the total degree of $f$ and $\deg_{t_i} f$ the degree of $f$ when it is treated as an element of $R'[t_i]$ where $R' = R[t_1, \ldots, t_{i-1}, t_{i+1}, \ldots, t_n]$. If $f$ is the zero polynomial of $R[t_1, \ldots, t_n]$, then we will assume that $\deg f = -\infty$, i.e., the zero polynomial is assumed to have a degree smaller than every non-zero polynomial. We will sometimes use the shorthand $R[t]$ for $R[t_1, \ldots, t_n]$ when $n$ is clear from the context.

A finite grid in $R^n$ (or $F^n$) is a subset $A$ of the form $A = A_1 \times \cdots \times A_n$ where $A_1, \ldots, A_n$ are finite nonempty subsets of $R$ (or $F$). For $f \in R[t_1, \ldots, t_n]$ and $A \subseteq R^n$, we put

$$Z_A(f) = \{x \in A \mid f(x) = 0\} \quad \text{and} \quad U_A(f) = \{x \in A \mid f(x) \neq 0\}.$$  

For $N, a_1, \ldots, a_n, b_1, \ldots, b_n \in \mathbb{Z}^+$, with $N \leq \sum_{i=1}^n a_i$ and $1 \leq b_i \leq a_i$ for all $i$, we denote by $m(a_1, \ldots, a_n; b_1, \ldots, b_n; N)$ a certain combinatorial quantity related to (restricted) distribution of $N$ balls in $n$ bins, which will be defined in Section 9.2. When $b_1 = \cdots = b_n = 1$ we denote this quantity by $m(a_1, \ldots, a_n; N)$.

---

3The problem asks if there exists a constant $c_n$ such that the minimum number of points in $F_q^n$ that contain a line in every direction is at least $c_n q^n$. 

---
8. Grid Reduction

8.1. Basics

One of the most basic results on polynomials is the fact that a single variable polynomial of degree \(d\) over an integral domain has at most \(d\) zeros. This result is clearly not true over arbitrary rings as one can see from the example \(f = t^2 - 1 \in \mathbb{Z}/8\mathbb{Z}[t]\) which has 4 zeros in \(\mathbb{Z}/8\mathbb{Z}\). To rectify this situation, we restrict to certain subsets of \(R\) that we now define.

Following [49] and [121], we say that a subset \(S\) of \(R\) satisfies Condition (D) if for every pair of distinct elements \(\alpha, \beta\) in \(S\), the element \(\alpha - \beta\) of \(R\) is not a zero divisor. We say that a finite grid \(A = A_1 \times \cdots \times A_n \subseteq R^n\) satisfies Condition (D) if every \(A_i\) satisfies Condition (D). Note that when \(R\) is an integral domain, this condition is automatically satisfied and in fact this is the case which most commonly occurs in combinatorial applications (with \(A\) being the binary grid \(\{0, 1\}^n\)). We will see that any single variable polynomial of degree \(d\) over a ring \(R\) has at most \(d\) zeros in any subset of \(R\) that satisfies Condition (D). But first, we mention some elementary results on polynomials over rings whose proofs are left to the reader.

**Lemma 8.1.1.** Let \(f, g, h \in R[t_1, \ldots, t_n]\) with \(f = g + h\).

1. If \(\deg f \geq \deg g\), then \(\deg f \geq \deg h\).
2. For all \(i \in \{1, \ldots, n\}\), if \(\deg_{t_i} f \geq \deg_{t_i} g\), then \(\deg_{t_i} f \geq \deg_{t_i} h\).

**Lemma 8.1.2.** Let \(f, g, h \in R[t_1, \ldots, t_n]\) with \(g\) monic and \(f = gh\). Then \(\deg f = \deg g + \deg h\).

**Lemma 8.1.3** (Euclidean Division Algorithm). Let \(f, g \in R[t]\) be single variable polynomials with \(g\) monic and nonzero. Then there exist polynomials \(h, r \in R[t]\) such that \(f = gh + r\) and \(\deg r < \deg g\).

**Corollary 8.1.4.** Let \(f \in R[t]\) be a single variable nonzero polynomial. If \(S \subseteq R\) is such that \(S\) satisfies Condition (D), then \(f\) has at most \(\deg f\) zeros in \(S\).

**Proof.** Let \(\alpha \in S\) be a zero of \(f\). We can write \(f = (t - \alpha)h + r\) with \(\deg r < 1\) (so \(r \in R\)). Substituting \(\alpha\) in the equation we see that \(r = 0\). Since \(f \neq 0\), we have \(h \neq 0\). Let \(\beta \in S \setminus \{\alpha\}\). Then \(f(\beta) = (\beta - \alpha)h(\beta)\). Since \(\beta - \alpha\) is not a zero divisor, \(f(\beta) = 0\) if and only if \(h(\beta) = 0\). Moreover, \(\deg h = \deg f - 1\) by Lemma 8.1.2. Thus, the result follows by induction on \(\deg f\).

\(^1\)We call a multivariate polynomial monic if the coefficient of its leading term, with respect to some monomial ordering, is 1. We could have also assumed that \(g \in R[t_i]\) for some \(i \in \{1, \ldots, n\}\) as that’s the only case which will be used later in the thesis.
In other words, if $f$ has more than $\deg f$ zeros in a set $S \subseteq R$ satisfying Condition (D), then $f = 0$. The following lemma is a generalization of this fact to multivariate polynomials.

**Lemma 8.1.5.** Let $R$ be a ring and let $A_1, \ldots, A_n$ be nonempty finite subsets of $R$ that satisfy Condition (D). Put $A := A_1 \times \cdots \times A_n$. Let $f \in R[t_1, \ldots, t_n]$ such that for all $i \in \{1, \ldots, n\}$ we have $\deg_{t_i} f \leq |A_i| - 1$. If $f(x) = 0$ for all $x \in A$, then $f = 0$.

**Proof.** We prove this by induction on $n$. The base case is clear from Corollary 8.1.4. For the inductive step write

$$f = \sum_{i=0}^{d_n} f_i(t_1, \ldots, t_{n-1})t_n^i,$$

where $d_n = \deg t_n f$. Let $x' \in A' = A_1 \times \cdots \times A_{n-1}$. Since $f(x) = 0$ for all $A$ we see that the single variable polynomial $f(x', t_n)$ vanishes everywhere on $A_n$. Since $\deg f(x', t_n) = d_n < |A_n|$, and $A_n$ satisfied Condition (D), Corollary 8.1.4 implies that $f(x', t_n)$ is the zero polynomial. This implies that for all $i$, $f_i(x') = 0$ for all $x' \in A'$. By the induction hypothesis, $f_i = 0$ for all $i$ and hence $f = 0$. \hfill $\square$

**Definition.** Let $A = A_1 \times \cdots \times A_n$ be a finite grid in $R^n$. Then a polynomial $f \in R[t_1, \ldots, t_n]$ is called $A$-reduced if for all $i \in \{1, \ldots, n\}$ we have $\deg_{t_i} f \leq |A_i| - 1$. We denote the set of all $A$-reduced polynomials by $\mathcal{R}_A$.

Therefore, Lemma 8.1.5 says that if a grid $A$ in $R^n$ satisfies Condition (D), then every $A$-reduced polynomial which vanishes at all points of $A$ must be equal to the zero polynomial. The following Lemma is a multivariate generalization of Lemma 8.1.3 and it will help us define the notion of grid reduction.

**Lemma 8.1.6.** Let $f \in R[t_1, \ldots, t_n]$ and let $g$ be a monic nonzero polynomial in $R[t_i]$ for some $i \in \{1, \ldots, n\}$. Then, there exist $h, r \in R[t_1, \ldots, t_n]$ such that

$$f = gh + r$$

and $\deg_{t_i} r < \deg g$. Moreover, $\deg h \leq \deg f - \deg g$, and $\deg r \leq \deg f$.

**Proof.** Without loss of generality, take $i = n$. Let $R' = R[t_1, \ldots, t_{n-1}]$. Then $f$ and $g$ can be seen as polynomials in $R'[t_n]$. If $\deg_{t_n} r < \deg g$, then we can take $h = 0$ and $r = f$. So, assume that $\deg_{t_n} r \geq \deg g$. By Lemma 8.1.3, $f = gh + r$ for some polynomials $h, r \in R'[t_n]$ such that $\deg r < \deg g$ and $h \neq 0$. If we now see $h$ and $r$ as polynomials in $R[t_1, \ldots, t_n]$ we get that $\deg_{t_n} r < \deg g$. Since $\deg_{t_n} r < d = \deg g$, for every monomial $t_1^{e_1} \cdots t_n^{e_n}$ in $h$ with $e_1 + \cdots + e_n = \deg h$ there exists a monomial $t_1^{e_1} t_2^{e_2} \cdots t_n^{e_n+d}$ in $f$. This shows that $\deg f \geq \deg h + \deg g$. Now from Lemmas 8.1.1 and 8.1.2, it follows that $\deg f \geq \deg g$. \hfill $\square$

Let $A = A_1 \times \cdots \times A_n$ be a finite grid in $R^n$. For each $i \in \{1, \ldots, n\}$, let $\varphi_i \in R[t_i]$ be the polynomial $\prod_{\lambda \in A_i} (t_i - \lambda)$ of degree $|A_i|$. We let $\Phi$ denote the ideal of $R[t_1, \ldots, t_n]$ generated by the polynomials $\varphi_1, \ldots, \varphi_n$. Then clearly $\Phi \subseteq I(A)$, where $I(A)$ is the ideal of all polynomials in $R[t_1, \ldots, t_n]$ that vanish on $A$. By repeated applications of Lemma 8.1.6 for every polynomial $f \in R[t_1, \ldots, t_n]$ we can find polynomials $g_1, \ldots, g_n \in R[t_1, \ldots, t_n]$ and $r \in \mathcal{R}_A$ such that

1. $f = g_1 \varphi_1 + \cdots + g_n \varphi_n + r$;
Grid Reduction

(2) \( \deg f \geq \deg r; \)

(3) \( \deg g_i \leq \deg f - \deg \varphi_i \) for all \( i \in \{1, \ldots, n\}. \)

This process is what we call the grid reduction of the polynomial \( f \) with respect to the finite grid \( A \). One can also define a more general notion of “Cartesian Reduction” by taking \( \varphi_i \)'s to be arbitrary monic polynomials in single variables, as was done by Clark in [49, Section 3]. It is also easy to show that the “remainder” \( r \) that one gets by this process of grid reduction is unique by proving that the ideal \( \Phi \) does not contain any \( A \)-reduced polynomials (see [49, Proposition 10]). We will denote this unique \( A \)-reduced polynomial that one gets after grid-reduction of \( f \) by \( r_A(f) \). From Lemma 8.1.5 we have the following result, which Clark calls the CATS Lemma [49, Theorem 12] (after Chevalley [47], Alon-Tarsi [5] and Schauz [121]).

**Lemma 8.1.7.** Let \( R \) be a ring and let \( A = A_1 \times \cdots \times A_n \) be a finite grid in \( R^n \). Then the following are equivalent:

1. \( A \) satisfies Condition (D);
2. If \( r \in R_A \) and \( r(x) = 0 \) for all \( x \in A \), then \( r = 0 \);
3. \( \Phi = I(A) \).

In particular, if \( A \) satisfies Condition (D), then for every polynomial \( f \), there exists a unique \( A \)-reduced polynomial \( r_A(f) \) such that \( f(x) = r_A(f)(x) \) for all \( x \in A \). Moreover, \( \deg f \geq \deg r_A(f) \).

**Proof.** (1) \( \implies \) (2) by Lemma 8.1.5. Let \( f \in I(A) \). From grid reduction, we get \( f = (\sum g_i \varphi_i) + r \), where \( r \) is \( A \)-reduced. Since \( f(x) = 0 \) for all \( x \in A \), we see that \( r(x) = 0 \) for all \( x \in A \), and hence \( r = 0 \) if (2) is assumed to be true. Therefore, (2) \( \implies \) (3). Now say (1) is false, and let \( \alpha, \beta \in A_i \) for some \( i \) with \( \alpha \neq \beta \), such that there exists a \( \gamma \in R \setminus \{0\} \) with \( \gamma(\alpha - \beta) = 0 \). Then the polynomial \( f = \gamma \prod_{\lambda \in A_i \setminus \{\alpha\}} (t_i - \lambda) \) is an \( A \)-reduced polynomial which is contained in \( I(A) \). But no \( A \)-reduced polynomial can be contained in \( \Phi \), and hence \( I(A) \neq \Phi \). Therefore, (3) \( \implies \) (1).

### 8.2. Applications of Grid Reduction

We first prove a lemma on zeros of polynomials in a finite grid, from which the Chevalley-Warning theorem, Jamison/Brouwer-Schrijver theorem on affine blocking sets, and the Alon-Füredi theorem on hyperplanes covering [3, Theorem 2] follow easily. We include the proof of the Chevalley-Warning theorem and discuss the other two results in Chapter 9 where they will follow from a more general result. Later on, we will see some other proofs of this Lemma as well.

**Lemma 8.2.1** (All Except One). Let \( f \in R[t_1, \ldots, t_n] \) and let \( A = A_1 \times \cdots \times A_n \) be a finite grid in \( R^n \) that satisfies Condition (D). If \( f \) vanishes on all points of \( A \) except one, then \( \deg f \geq \sum (|A_i| - 1) \).
Proof. Let \( a = (a_1, \ldots, a_n) \) be the point where \( f \) doesn’t vanish. The polynomial

\[
g(t) = \prod_{i=1}^{n} \prod_{\lambda \in A_i \backslash \{a_i\}} (t_i - \lambda)
\]

of degree \( \sum(|A_i| - 1) \) is an \( A \)-reduced polynomial that vanishes everywhere on \( A \) except at \( a \). Therefore, the polynomial \( g(a)r_A(f) - f(a)g \) is an \( A \)-reduced polynomial that vanishes everywhere on \( A \), which implies that \( g(a)r_A(f) = f(a)g \) by Lemma 8.1.7. Since \( \deg r_A(f) = \deg g \) and \( \deg f \geq \deg r_A(f) \), we get \( \deg f \geq \deg g = \sum_{i=1}^{n}(|A_i| - 1) \).

\[\square\]

Remark. When \( R \) is a field, Lemma 8.2.1 appears implicitly in [27] where several applications of this lemma in finite geometry are explored.

**Theorem 8.2.2** (Chevvalley-Warning Theorem [47,139]). Let \( f_1, \ldots, f_r \in \mathbb{F}_q[t_1, \ldots, t_n] \) be such that \( \sum_{i=1}^{r} \deg f_i < n \) and let \( Z \) be the set of common zeros of \( f_1, \ldots, f_r \) in \( \mathbb{F}_q^n \). Then \( |Z| \neq 1 \).

Proof. Define a polynomial \( f \in \mathbb{F}_q[t_1, \ldots, t_n] \) by \( f = \prod_{i=1}^{r} (1 - f_i^{q-1}) \). Then since \( \lambda^{q-1} = 1 \) for every \( \lambda \in \mathbb{F}_q \setminus \{0\} \), we have \( f(x) = 1 \) if \( x \in Z \) and \( f(x) = 0 \) if \( x \notin Z \). Say \( |Z| = 1 \). Then \( f \) vanishes on all points of the grid \( \mathbb{F}_q^n \) except one point. Therefore, by Lemma 8.2.1, we have \( \deg f = (q-1) \sum_{i=1}^{r} \deg f_i \geq n(q-1) \). This contradicts the fact that \( \sum_{i=1}^{r} \deg f_i < n \).

\[\square\]

In fact, one can as easily prove Brink’s generalization of Chevvalley-Warning theorem [29] using Lemma 8.2.1 (also see [49, Theorem 19]).

**Theorem 8.2.3** (Restricted Variable Chevvalley-Warning Theorem). Let \( f_1, \ldots, f_r \in \mathbb{F}_q[t_1, \ldots, t_n] \) and let \( A_1, \ldots, A_n \) be nonempty subsets of \( \mathbb{F}_q \). Let \( Z_A = \{ x \in \prod A_i \mid \forall j \ f_j(x) = 0 \} \). If \( (q-1) \) \( \sum \deg f_j \) which is equal to \( 1 \) on all common zeros of \( f_j \)'s and \( 0 \) otherwise. Then \( Z_A \) corresponds to the set of non-zeros of \( f \) in \( A = A_1 \times \cdots \times A_n \). Say \( |Z_A| = 1 \). Then by Lemma 8.2.1 we have \( \deg f = (q-1) \sum \deg f_j \geq \sum(|A_i| - 1) \), which is a contradiction.

\[\square\]

Next we see a proof of Alon’s Combinatorial Nullstellensatz [1] that uses the ideas of grid reduction developed so far. We note that this proof is essentially the same as the proof given by Alon in [1]. Its generalization over rings is due to Schauz [121] and the idea of looking at this proof in the following way is due to Clark [49].

**Theorem 8.2.4** (Combinatorial Nullstellensatz for Rings). Let \( f \in R[t_1, \ldots, t_n] \) and let \( A = A_1 \times \cdots \times A_n \) be a finite grid in \( R^n \) that satisfies Condition (D). For all \( i \in \{1, \ldots, n\} \), define \( \varphi_i = \prod_{\lambda \in A_i} (t_i - \lambda) \).

1. If \( f \) vanishes on all points of \( A \), then there exist \( g_1, \ldots, g_n \) such that \( f = \sum g_i \varphi_i \) and \( \deg g_i \leq \deg f - \deg \varphi_i \) for all \( i \).

2. If there is a monomial term \( \prod t_i^{d_i} \) in \( f \) with the property that \( d_1 + \cdots + d_n = \deg f \) and \( d_i < \deg \varphi_i = |A_i| \) for all \( i \), then \( f \) doesn’t vanish everywhere on \( A \).

Proof. Reduce \( f \) modulo the grid \( A \). Then \( r_A(f) \) vanishes everywhere on \( A \), and hence by Lemma 8.1.5, it must be zero. For (2) observe that such a monomial term is not affected by grid reduction, and hence the reduced form \( r_A(f) \) is non-zero. If \( f \) vanishes
everywhere on \( A \), then \( r_A(f) \) also vanishes everywhere on \( A \), which is not possible as it would contradict Lemma \[8.1.5\].

We now give a simple proof of a variation of Ball and Serra’s Punctured Combinatorial Nullstellensatz \[13,14\] over rings.\footnote{This generalization is due to Clark \[50\], but our proof is different from his.}

**Lemma 8.2.5.** Let \( A = A_1 \times \cdots \times A_n \) be a finite grid in \( \mathbb{R}^n \) that satisfies Condition (D). Let \( f \in R[t_1, \ldots, t_n] \) be \( A \)-reduced and let \( \lambda \in A_i \) for some \( i \). If \( f_\lambda = f(t_1, \ldots, t_{i-1}, \lambda, t_{i+1}, \ldots, t_n) \) vanishes everywhere on \( A_1 \times \cdots \times A_{i-1} \times A_{i+1} \times \cdots \times A_{n-1} \), then \( t_i - \lambda \) divides \( f \).

**Proof.** Using Lemma \[8.1.6\] write \( f = (t_i - \lambda)h + r \) with \( \deg_t r < 1 \), i.e., \( r \) can be considered as an element of \( R[t_1, \ldots, t_{i-1}, t_{i+1}, \ldots, t_n] \). From Lemma \[8.1.1\] it follows that \( r \) is also \( A \)-reduced. Say \( f_\lambda = r \) vanishes everywhere. Then by Lemma \[8.1.5\] we get \( r = 0 \), i.e., \( t_i - \lambda \) divides \( f \).

**Theorem 8.2.6 (Punctured Combinatorial Nullstellensatz for Rings).** Let \( f \in R[t_1, \ldots, t_n] \) and let \( A = A_1 \times \cdots \times A_n \) be a finite grid in \( \mathbb{R}^n \) that satisfies Condition (D). Let \( B_1, \ldots, B_n \) be nonempty subsets of \( A_1, \ldots, A_n \), respectively, and put \( B = B_1 \times \cdots \times B_n \). For \( i \in \{1, \ldots, n\} \), define \( \varphi_i = \prod_{\lambda \in A_i} (t_i - \lambda) \). If \( f \) vanishes on all points of \( A \setminus B \) and does not vanish on at least one point of \( B \), then there exist polynomials \( g_1, \ldots, g_n \) such that \( f = \sum g_i \varphi_i + r \) where \( r \in R_A \) is a non-zero multiple of the polynomial \( \prod_{i=1}^n \prod_{\lambda \in A_i \setminus B_i} (t_i - \lambda) \) and \( \deg g_i \leq \deg f - \deg \varphi_i \) for all \( i \). Moreover, \( \deg f \geq \deg r \geq \sum (|A_i| - |B_i|) \).

**Proof.** Apply grid reduction on \( f \) with respect to \( A \) to get \( f = \sum g_i \varphi_i + r \), such that \( \deg g_i \leq \deg f - \deg \varphi_i \) for all \( i \), and \( \deg f \geq \deg r \). Then, we just have to show that \( \prod_{i=1}^n \prod_{\lambda \in A_i \setminus B_i} (t_i - \lambda) \) divides \( r \).

Let \( \lambda \in A_1 \setminus B_1 \). By the given condition on \( f \), the polynomial \( r(\lambda, t_2, \ldots, t_n) \) vanishes everywhere on \( A_2 \times \cdots \times A_n \). Now from Lemma \[8.2.5\] it follows that \( t_1 - \lambda \) divides \( r \). Write \( r = (t_1 - \lambda)r' \). Say \( \lambda' \in A_1 \setminus B_1 \) with \( \lambda' \neq \lambda \), then we see that \( r(\lambda', t_2, \ldots, t_n) = (\lambda' - \lambda)r'(\lambda', t_2, \ldots, t_n) \) vanishes everywhere on \( A_2 \times \cdots \times A_n \), and hence is equal to 0 by Lemma \[8.2.5\]. Since \( \lambda' - \lambda \) is not a zero divisor, the polynomial \( r'(\lambda', t_2, \ldots, t_n) \) must be equal to 0, which implies that \( (t_1 - \lambda') \) divides \( r' \). Continuing in this manner, we get that \( \psi(t_1) = \prod_{\lambda \in A_1 \setminus B_1} (t_1 - \lambda) \) divides \( r \).

Now we show that \( \psi(t_2) = \prod_{\lambda \in A_2 \setminus B_2} (t_2 - \lambda) \), which also divides \( r \) by a similar reasoning, must in fact divide \( r/\psi(t_1) \). Write \( r = \psi(t_1)r_1 \). Take a \( \lambda \in A_2 \setminus B_2 \). Then \( r(t_1, \lambda, t_3, \ldots, t_n) = \psi(t_1)r_1(t_1, \lambda, t_3, \ldots, t_n) \) is equal to the zero polynomial by Lemmas \[8.2.5\] and \[8.1.6\]. Since \( \psi(t_1) \) is a monic non-zero polynomial, the polynomial \( r_1(t_1, \lambda, t_3, \ldots, t_n) \) must be equal to 0 by Lemma \[8.1.2\] and hence \( t_2 - \lambda \) divides \( r_1 \). Therefore, \( \psi(t_1) \psi(t_2) \) divides \( r \). Continuing in this manner, we get the result.

Note that Lemma \[8.2.1\] and hence all of its consequences, also follow from Theorem \[8.2.6\] by taking all \( B_i \)'s to be singleton.

\footnote{In fact, the same proof gives us Lasoni’s generalization of Combinatorial Nullstellensatz \[?\].}

\footnote{It’s a variation in the sense that we do not take multiplicities into account and we work over grids satisfying Condition (D) over a ring.}
8.3. Punctured Chevalley-Warning

From Theorem 8.2.6 over fields, we obtain a new generalization of the Chevalley-Warning theorem which we call Punctured Chevalley-Warning Theorem.

**Theorem 8.3.1.** Let $A_1, \ldots, A_n, B_1, \ldots, B_n$ be nonempty finite subsets of $\mathbb{F}_q$ such that for all $i$ we have $B_i \subseteq A_i$. Put $A = A_1 \times \cdots \times A_n$ and $B = B_1 \times \cdots \times B_n$. Let $f_1, \ldots, f_r \in \mathbb{F}_q[t_1, \ldots, t_n]$ be such that $(q - 1) \sum_{j=1}^r \deg f_j < \sum (|A_i| - |B_i|)$ and let $Z_A = \{ x \in \prod A_i \mid \forall j f_j(x) = 0 \}$. If $Z_A \cap B \neq \emptyset$, then $Z_A \cap (A \setminus B) \neq \emptyset$.

**Proof.** Let $f = \prod_{j=1}^r (1 - f_j^{q-1})$. Then we are given that $\deg f = (q - 1) \sum \deg f_j < \sum (|A_i| - |B_i|)$. Say $Z_A \cap B \neq \emptyset$ and $Z_A \cap (A \setminus B) = \emptyset$. Then $f$ vanishes everywhere on $A$, except at some point of $B$. Therefore, we get the contradiction from Theorem 8.2.6 which says that $\deg f = (q - 1) \sum \deg f_j$ must be at least $\sum (|A_i| - |B_i|)$.

Again by taking $B_i$’s to be singletons we get Theorem 8.2.3 from Theorem 8.3.1. The following two direct corollaries of Theorem 8.3.1 might be of independent interest.

**Corollary 8.3.2.** Let $q$ be a prime power and let $f_1, \ldots, f_r$ be polynomials in $\mathbb{F}_q[t_1, \ldots, t_n]$, with $\sum \deg f_i < n(q - 2)/(q - 1) = n - n/(q - 1)$. If $f_1, \ldots, f_r$ have a common zero in $\{0, 1\}^n$, then they have a common zero in $\mathbb{F}_q^n \setminus \{0, 1\}^n$.

**Corollary 8.3.3.** Let $q$ be a prime power and $s$ a positive integer and let $\mathbb{F}_q \subset \mathbb{F}_{q^s}$ be a field extension. Let $f_1, \ldots, f_r$ be polynomials in $\mathbb{F}_q[t_1, \ldots, t_n]$, with $\sum \deg f_i < n(q^s - q)/(q^s - 1) = n - n/(1 + q + \cdots + q^{s-1})$. If $f_1, \ldots, f_r$ have a common zero in $\mathbb{F}_q^n$, then they have a common zero in $\mathbb{F}_{q^s}^n \setminus \mathbb{F}_q^n$.

**Remark.** In the setting of Corollary 8.3.3 let $N_s$ denote the number of common zeros of the polynomials in $\mathbb{F}_q^n$. Then the result gives a condition on the sum of degrees which ensures that $N_s > N_1$. 
9. Alon-Füredi Theorem

9.1. Introduction

In [3], Alon and Füredi solved a problem posed by Bárány (based on a paper of Komjáth [99]) of finding the minimum number of hyperplanes required to cover all points of the hypercube \( \{0,1\}^n \subseteq F^n \) except one. One such covering is given by \( n \) hyperplanes defined by the zeros of the polynomials \( t_1 - 1, t_2 - 1, \ldots, t_n - 1 \). Alon and Füredi proved that \( n \) is in fact the minimum number. They then generalized this result to all finite grids \( A = \prod_{i=1}^n A_i \subseteq F^n \), showing that the minimum number of hyperplanes required to cover all points of \( A \) except one is \( \sum_{i=1}^n (|A_i| - 1) \).

There is also a quantitative refinement: as we vary over families of \( d \) hyperplanes which do not cover all points of \( A \), what is the minimum number of points that are missed? To answer this, Alon and Füredi proved the following result.

**Theorem 9.1.1** (Alon-Füredi Theorem [3, Theorem 5]). Let \( F \) be a field, let \( A = \prod_{i=1}^n A_i \subseteq F^n \) be a finite grid, and let \( f \in F[t] \) be a polynomial which does not vanish on all points of \( A \). Then \( f(x) \neq 0 \) for at least \( \min\{\prod y_i\} \) elements \( x \in A \), where the minimum is taken over all positive integers \( y_i \leq |A_i| \) with \( \sum_{i=1}^n y_i = \sum_{i=1}^n |A_i| - \deg f \).

More concisely (see Section 9.2 for the notation)

\[
|U_A(f)| \geq m(|A_1|, \ldots, |A_n|; \sum_{i=1}^n |A_i| - \deg f).
\]

Several proofs of Theorem 9.1.1 have been given. The original argument in [3] involves constructing auxiliary polynomial functions of low degree via linear algebra. A second proof was given by Ball and Serra as an application of Theorem 8.2.6 over fields. Recently, López, Rentería-Márquez and Villarreal gave a proof of Alon-Füredi in its coding theoretic formulation [107] (this will be discussed in Section 9.6). In [83], Geil showed that the minimum distance of generalized Reed-Muller codes can be determined easily using Gröbner basis theory [83, Theorem 2]. This technique was then used by Carvalho to give another proof of Theorem 9.1.1 when \( F \) is a finite field, [45, Proposition 2.3], which is in fact a special case of an earlier result by Geil and Thomsen [84, Proposition 5] (take all weights equal to 1).

In [50], Clark generalized the Alon-Füredi Theorem by replacing the field \( F \) by an arbitrary ring \( R \), under the assumption that the finite grid \( A \) satisfies Condition (D), which as we have seen in Chapter 8 is exactly what is needed for polynomial functions on \( A \) to behave as they do in the case of a field. His proof adapts that of Ball and Serra.

\footnote{This result follows directly from Lemma 8.2.1 by associating the hyperplanes to linear polynomials that define them and then taking the product of these polynomials.}
Clark, Forrow and Schmitt \[51\] used Alon-Füredi to obtain a restricted variable general-
ization of a theorem of Warning \[139\] which gives a lower bound on the number of zeros of
a system of polynomials over a finite field. Alon-Füredi gives a lower bound on non-zeros,
but over a finite field \(\mathbb{F}_q\), we have Chevalley’s trick: \(f(x) = 0 \iff 1 - f(x)^{q-1} \neq 0\) (see
the proof of Theorem \[8.2.2\]). This work also gave several combinatorial applications of this
lower bound on restricted variable zero sets.

In this chapter, we will revisit the Alon-Füredi Theorem and give direct combinatorial
applications (i.e., not of Chevalley-Warning type). We will also prove the following gen-
eralization of this result which, along with the total degree, takes the degrees of the
polynomial in individual variables in account as well.

**Theorem 9.1.2** (Generalized Alon-Füredi Theorem). \(\) Let \(R\) be a ring and let \(A_1, \ldots, A_n\)
be nonempty finite subsets of \(R\) that satisfy Condition (D). For \(i \in \{1, \ldots, n\}\), let \(a_i = |A_i|\)
and let \(b_i\) be an integer such that \(1 \leq b_i \leq a_i\). Let \(f \in R[t]\) be a non-zero polynomial
such that \(\deg_{t_i} f \leq a_i - b_i\) for all \(i \in \{1, \ldots, n\}\). Let \(U_A = \{x \in A \mid f(x) \neq 0\}\) where
\(A = A_1 \times \cdots \times A_n \subseteq R^n\). Then we have (see Section 9.2 for the notation)
\[
|U_A| \geq m(a_1, \ldots, a_n; b_1, \ldots b_n; \sum_{i=1}^{n} a_i - \deg f).
\]
Moreover, for any such \(R, A_1, \ldots, A_n\) and integers \(b_1, \ldots, b_n\), we can construct a polyno-
mial \(f\) which meets this bound.

**Remark.** Some justification is required for calling Theorem 9.1.2 a “Generalized” Alon-
Füredi Theorem. If \(f \in F[t_1, \ldots, t_n]\) is a polynomial that does not vanish on all points of
a finite grid \(A\), then by Lemma 8.1.7 there exists a unique non-zero \(A\)-reduced polynomial
\(r_A(f)\) which takes the same values on \(A\) as \(f\). We can use the polynomial \(r_A(f)\), whose
degree is at most \(\deg f\), to show that Theorem 9.1.1 follows from Theorem 9.1.2 (we need
Lemma 9.2.3 as well).

In Section 9.4 we relate the Generalized Alon-Füredi Theorem to work of DeMillo-Lipton,
Schwartz and Zippel. We find in particular that Alon-Füredi implies the result which has
become known as the “Schwartz-Zippel Lemma”. In fact, the original result of Zippel (and
earlier, DeMillo-Lipton) is a bit different and not implied by Alon-Füredi (cf. Example 9.4). However, it is implied by Generalized Alon-Füredi, and this was one of our moti-
vations for strengthening Alon-Füredi as we have. In Section 9.5 we discuss multiplicity
enhancements in the sense of \[78\].

The Alon-Füredi Theorem has a natural coding theoretic interpretation (see Section 9.6)
as it computes the minimum Hamming distance of the affine grid code \(\text{AGC}_d(A)\), an \(F\)-
linear code of length \(|A|\). In this way Alon-Füredi turns out to be the restricted variable
generalization of a much older result in the case \(A_i = F = \mathbb{F}_q\), the Kasami-Lin-Peterson
Theorem, which computes the minimum Hamming distance of generalized Reed-Muller
codes. We will show that the Generalized Alon-Füredi Theorem is equivalent to the
computation of the minimum Hamming distance of a more general class of \(R\)-linear codes.
These generalized affine grid codes have larger distance (though also smaller dimension)
than the standard ones, so they may turn out to be useful.

In Section 9.7 we pursue applications to finite geometry. We begin by revisiting and
slightly sharpening the original result of Alon-Füredi on hyperplane coverings. This nat-
Alon-Füredi Theorem

naturally leads us to partial covers and blocking sets in affine and projective geometries over \( \mathbb{F}_q \). Applying Alon-Füredi and projective duality we get a new upper bound, Theorem 9.7.6, on the number of hyperplanes which do not meet a \( k \)-element subset of \( \text{AG}(n, q) \).

From this result the classical theorems of Jamison-Brouwer-Schrijver on affine blocking sets and Blokhuis-Brouwer on essential points of projective blocking sets follow as corollaries. We are also able to strengthen a recent result of Dodunekov, Storme and Van de Voorde.

When combined with the work done by Clark, Forrow and Schmitt in [50, 51], our work demonstrates that the Alon-Füredi theorem, much like the Combinatorial Nullstellensatz, is a fundamental result on polynomials with connections to various important topics in mathematics. Thus we hope to convince the reader that this is an important tool to possess for those working in areas where polynomial methods might be successful.

9.2. Balls in Bins

Let \( a_1, \ldots, a_n \in \mathbb{Z}^+ \). Consider \( n \) bins \( A_1, \ldots, A_n \) such that \( A_i \) can hold up to \( a_i \) balls for every \( i \in \{1, \ldots, n\} \). For \( N \in \mathbb{Z}^+ \) with \( n \leq N \leq \sum_{i=1}^n a_i \), we define a distribution of \( N \) balls in these \( n \) bins to be an \( n \)-tuple \( y = (y_1, \ldots, y_n) \in (\mathbb{Z}^+)^n \) with \( y_i \leq a_i \) for all \( i \in \{1, \ldots, n\} \) and \( \sum_{i=1}^n y_i = N \). For a distribution \( y \) of \( N \) balls in \( n \) bins, we put \( P(y) = \prod_{i=1}^n y_i \). For \( n \leq N \leq \sum_{i=1}^n a_i \) we define \( m(a_1, \ldots, a_n; N) \) to be the minimum value of \( P(y) \) as \( y \) ranges over all such distributions of \( N \) balls in \( n \) bins. For \( N < n \) we define \( m(a_1, \ldots, a_n; N) = 1 \).

Without loss of generality we may assume \( a_1 \geq \cdots \geq a_n \). We define the greedy distribution \( y_G = (y_1, \ldots, y_n) \) as follows: first place one ball in each bin; then place the remaining balls into bins from left to right, filling each bin completely before moving on to the next bin, until we run out of balls. Then an easy argument shows the following.

**Lemma 9.2.1.** Let \( n \in \mathbb{Z}^+ \), and let \( a_1 \geq \cdots \geq a_n \) be positive integers. Let \( N \in \mathbb{Z}^+ \) with \( n \leq N \leq a_1 + \cdots + a_n \).

1. We have \( m(a_1, \ldots, a_n; N) = P(y_G) = y_1 \cdots y_n \).

2. Suppose \( a_1 = \cdots = a_n = a \geq 2 \). Then
   \[
   m(a, \ldots, a; N) = (r + 1)a^{\left\lfloor \frac{N-n}{a-1} \right\rfloor},
   \]
   where \( r \equiv N - n \pmod{a - 1} \) and \( 0 \leq r < a - 1 \).

3. For all non-negative integers \( k \), we have
   \[
   m(2, \ldots, 2; 2n - k) = 2^{n-k}.
   \]

4. Let \( n, a_1, \ldots, a_n \in \mathbb{Z}^+ \) with \( a_1 \geq \cdots \geq a_n \). Let \( N \in \mathbb{Z}^+ \) be such that \( N - n = \sum_{i=1}^j (a_i - 1) + r \) for some \( j \in \{0, \ldots, n\} \) and some \( r \) satisfying \( 0 \leq r < a_{j+1} \). Then \( m(a_1, \ldots, a_n; N) = (r + 1)\prod_{i=1}^j a_i \).
In general, we do not know a simple description of \( b \), we are left with \( m \). (4) After placing one ball in each bin we are left with \( N - n \) balls. The greedy distribution is achieved by filling the first \( j \) bins entirely and then putting \( r \) balls in bin \( j + 1 \). Note that (2) is a special case of (4).  

Proof. Parts (1) through (3) are [51, Lemma 2.2]. (4) After placing one ball in each bin we are left with \( N - n \) balls. The greedy distribution is achieved by filling the first \( j \) bins entirely and then putting \( r \) balls in bin \( j + 1 \). Note that (2) is a special case of (4).  

In every distribution \( y = (y_1, \ldots, y_n) \) we need \( y_i \geq 1 \) for all \( i \in \{1, \ldots, n\} \); i.e., we must place at least one ball in each bin. So it is reasonable to think of the bins coming prefilled with one ball each, and then our task is to distribute the \( N - n \) remaining balls so as to minimize \( P(y) \). The concept of prefilled bins makes sense more generally: given any \( b_1, \ldots, b_n \in \mathbb{Z} \) with \( 1 \leq b_i \leq a_i \), we may consider the scenario in which the \( i \)-th bin comes prefilled with \( b_i \) balls. If \( \sum_{i=1}^n b_i \leq N \leq \sum_{i=1}^n a_i \), we may restrict to distributions \( y = (y_1, \ldots, y_n) \) of \( N \) balls into bins of sizes \( a_1, \ldots, a_n \) such that \( b_i \leq y_i \leq a_i \) for all \( i \in \{1, \ldots, n\} \) and then we put

\[
m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) = \min P(y),
\]

where the minimum ranges over this restricted set of distributions. For \( N < \sum_{i=1}^n b_i \) we define \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) := \prod_{i=1}^n b_i \).

**Lemma 9.2.2.** We have \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) = \prod_{i=1}^n b_i \iff N \leq \sum_{i=1}^n b_i \).

Proof. If \( N \leq \sum_{i=1}^n b_i \) then \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) = \prod_{i=1}^n b_i \) by definition unless \( N = \sum_{i=1}^n b_i \), and this case is immediate: we have exactly enough balls to perform the prefilling. If \( N > \sum_{i=1}^n b_i \), then \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) \) is the minimum over a set of integers each of which is strictly greater than \( \prod_{i=1}^n b_i \).  

In this prefilled context, the greedy distribution \( y_G \) is defined by starting with the bins prefilled with \( b_1, \ldots, b_n \) balls and then distribute the remaining balls from left to right, filling each bin completely before moving on to the next bin. One sees, for example by adapting the argument of [51, Lemma 2.2], that

\[
m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) = P(y_G)
\]

when we also have \( b_1 \geq \cdots \geq b_n \). But this may not hold in general, as the following example shows.

**Example.** Let \( n = 2, a_1 = 4, a_2 = 3, b_1 = 1, b_2 = 2, N = 4 \). Then \( P(y_G) = 4 \) but \( m(4, 3; 1, 2; 4) = 3 \) achieved by the distribution \((1, 3)\).

In general, we do not know a simple description of \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) \). In practice, it can be computed using dynamic programming. The following properties of this combinatorial function will play an important role in our proof.

**Lemma 9.2.3.** Let \( a_1, \ldots, a_n, b_1, \ldots, b_n \in \mathbb{Z}^+ \) with \( 1 \leq b_i \leq a_i \) for all \( i \in \{1, \ldots, n\} \). Let \( N_1, N_2 \in \mathbb{Z} \) such that \( N_1 \leq N_2 \leq \sum_{i=1}^n a_i \). Then

\[
m(a_1, \ldots, a_n; b_1, \ldots, b_n; N_1) \leq m(a_1, \ldots, a_n; b_1, \ldots, b_n; N_2).
\]

Proof. If \( N_2 \leq \sum b_i \), then both these quantities are equal by Lemma 9.2.2. For \( N_1 \leq \sum b_i < N_2 \), we have strict inequality. So assume that \( \sum b_i < N_1 < N_2 \leq \sum a_i \). Let \( y \) be a distribution of \( N_2 \) balls for which \( P(y) = m(a_1, \ldots, a_n; b_1, \ldots, b_n; N_2) \). From this distribution we can remove \( N_2 - N_1 \geq 1 \) balls without violating any conditions, which gives us a new distribution \( y' \) of \( N_1 \) balls. We must have \( P(y') < P(y) \) and hence \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N_1) \leq P(y') < P(y) = m(a_1, \ldots, a_n; b_1, \ldots, b_n; N_2) \).
**Lemma 9.2.4.** Let \( a_1, \ldots, a_n, b_1, \ldots, b_n \in \mathbb{Z}^+ \) with \( 1 \leq b_i \leq a_i \) for all \( i \in \{1, \ldots, n\} \). Let \( k \in \mathbb{Z} \) such that \( b_n \leq k \leq a_n \). If
\[
b_1 + \cdots + b_{n-1} \leq N - k \leq a_1 + \cdots + a_{n-1}
\]
for some \( N \in \mathbb{Z} \), then
\[
k \cdot m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; N - k) \geq m(a_1, \ldots, a_n; b_1, \ldots, b_n; N).
\]

**Proof.** Let \( y' = (y_1, \ldots, y_{n-1}) \) be a distribution of \( N - k \) balls in the first \( n - 1 \) bins. Then \( y = (y_1, \ldots, y_{n-1}, k) \) is a distribution of \( N \) balls in \( n \) bins with the last bin getting \( k \) balls. Therefore,
\[
m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) \leq P(y) = k \cdot P(y').
\]
Since this holds for all such distributions \( y' \), we get
\[
m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) \leq k \cdot m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; N - k).
\]

\[\square\]

### 9.3. Proof of Generalized Alon-Füredi Theorem

We go by induction on \( n \).

**Base Case:** Let \( f \in R[t_1] \) be a nonzero polynomial. Suppose \( f \) vanishes precisely at the distinct elements \( x_1, \ldots, x_k \) of \( A_1 \). By Corollary [8.1.4] we have
\[
|U_{A}(f)| = a_1 - k \geq a_1 - \deg f,
\]
which is the conclusion of the Generalized Alon-Füredi Theorem in this case.

**Induction Step:** Suppose \( n \geq 2 \) and the result holds for \( n - 1 \). Write
\[
f(t_1, \ldots, t_n) = \sum_{i=0}^{d_n} f_i(t_1, \ldots, t_{n-1})t_n^i,
\]
so that \( d_n = \deg_{t_n} f \) is the largest index \( i \) such that \( f_i \neq 0 \). Moreover we have \( \deg f - d_n \leq \deg f \) and for all \( i \in \{1, \ldots, n-1\}, \deg_{t_i} f_{d_n} \leq \deg_{t_i} f \leq a_i - b_i \). Put \( A' = \prod_{i=1}^{n-1} A_i \). By the induction hypothesis, we have
\[
|U_{A'}(f_{d_n})| \geq m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; \sum_{i=1}^{n-1} a_i - \deg f_{d_n})
\]
\[
\geq m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; \sum_{i=1}^{n-1} a_i - \deg f + d_n), \text{ by Lemma } 9.2.3
\]
Let \( x' = (x_1, \ldots, x_{n-1}) \in U_{A'}(f_{d_n}) \). Then \( f(x', t_n) = \sum_{i=0}^{d_n} f_i(x')t_n^i \in R[t_n] \) has degree \( d_n \geq 0 \) since its leading term \( f_{d_n}(x')t_n^{d_n} \) is non-zero. Since \( A_n \) satisfies Condition (D),
$f(x', t_n)$ vanishes at no more than $d_n$ points of $A_n$ by Corollary 8.1.4, so there are at least $a_n - d_n$ elements $x_n \in A_n$ such that $(x', x_n) \in U_A(f)$. Thus

$$|U_A(f)| \geq (a_n - d_n) \cdot m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; \sum_{i=1}^{n-1} a_i - \deg f + d_n).$$

Since

$$\deg f \leq \sum_{i=1}^{n} \deg_{t_i} f = \sum_{i=1}^{n-1} \deg_{t_i} f + d_n$$

and thus

$$\sum_{i=1}^{n} b_i \leq \sum_{i=1}^{n-1} (a_i - \deg_{t_i} f) \leq \sum_{i=1}^{n-1} a_i - \deg f + d_n \leq \sum_{i=1}^{n} a_i,$$

we may apply Lemma 9.2.4 with $N = \sum_{i=1}^{n} a_i - \deg f$ and $k = a_n - d_n$, getting

$$(a_n - d_n) \cdot m(a_1, \ldots, a_{n-1}; b_1, \ldots, b_{n-1}; \sum_{i=1}^{n-1} a_i - \deg f + d_n) \geq m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} a_i - \deg f).$$

We deduce that

$$|U_A(f)| \geq m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} a_i - \deg f).$$

### 9.3.1. Sharpness of the Generalized Alon-Füredi Bound

Let $d$ be an integer such that $0 \leq d \leq \sum_{i=1}^{n} (a_i - b_i)$ for any distribution $y = (y_1, \ldots, y_n)$ of $\sum_{i=1}^{n} a_i - d$ balls in $n$ bins with $b_i \leq y_i \leq a_i$, for all $i$ choose a subset $S_i \subseteq A_i$ of cardinality $a_i - y_i$, and put

$$f(t) = \prod_{i=1}^{n} \prod_{x_i \in S_i} (t_i - x_i).$$

Then

$$\deg f = \sum_{i=1}^{n} (a_i - y_i) = d,$$

for all $i \in \{1, \ldots, n\}$, $\deg_{t_i} f = a_i - y_i \leq a_i - b_i$

and

$$U_A(f) = P(y) = \prod_{i=1}^{n} y_i.$$

Thus, for all finite grids $A = \prod_{i=1}^{n} A_i$ satisfying Condition (D) and all permissible values of $\deg_{t_1} f, \ldots, \deg_{t_n} f$ and $\deg f$, there are instances of equality in the Generalized Alon-
Füredi Bound. The case $b_1 = \cdots = b_n = 1$ yields the (known) sharpness of the Alon-Füredi Bound.

### 9.4. Connections with the Schwartz-Zippel Lemma

The following result originated in computer science literature related to the Polynomial Identity Testing (PIT) problem where the aim is to design an “efficient” way of determining whether a given multivariate polynomial over a field $F$ is identically equal to the zero polynomial (see [124, Chapter 4] for a survey and the precise problem statement). It is now known as the Schwartz-Zippel Lemma after the independent works of Schwartz [122] and Zippel [143].

**Theorem 9.4.1 (Schwartz-Zippel Lemma).** Let $R$ be an integral domain and let $S \subseteq R$ be finite and nonempty. Let $f \in R[t_1, \ldots, t_n]$ be a nonzero polynomial. Then

$$|Z_S^n(f)| \leq (\deg f)|S|^{n-1}.$$ 

This Lemma has a curious history, as recorded in the blog post of Lipton [106]. An earlier paper due to De Millo and Lipton [73] proves a similar result which is in fact sufficient for the applications to the PIT problem. This result of DeMillo and Lipton is also what Zippel proved in [143].

**Theorem 9.4.2 (DeMillo-Lipton-Zippel Theorem).** Let $R$ be an integral domain, let $f \in R[t_1, \ldots, t_n]$, and let $d$ be a positive integer such that $\deg t_i f \leq d$ for all $i \in \{1, \ldots, n\}$. Let $S$ be a finite subset of $R$ with more than $d$ elements. Then

$$|Z_S^n(f)| \leq |S|^n - (|S| - d)^n.$$ 

Schwartz proved Theorem 9.4.1 as a corollary of the following more general upper bound.

**Theorem 9.4.3 (Schwartz Theorem [122, Lemma 1]).** Let $R$ be an integral domain, $f = f_n \in R[t_1, \ldots, t_n]$ be a nonzero polynomial and let $d_n = \deg_t f_n$. Let $f_{n-1} \in R[t_1, \ldots, t_{n-1}]$ be the coefficient of $t_n^d_n$ in $f_n$. Let $d_{n-1} = \deg_t f_{n-1}$, and let $f_{n-2} \in R[t_1, \ldots, t_{n-2}]$ be the coefficient of $t_{n-1}^{d_{n-1}}$ in $f_{n-1}$. Continuing in this manner we define for all $i \in \{1, \ldots, n\}$ a polynomial $f_i \in R[t_1, \ldots, t_i]$ with $\deg_t f_i = d_i$. Let $A = A_1 \times \cdots \times A_n$ be a finite grid in $R^n$. Then

$$|Z_A(f)| \leq |A| \sum_{i=1}^n \frac{d_i}{|A_i|}.$$ 

Interestingly, the DeMillo-Lipton-Zippel theorem does not imply the Schwartz-Zippel lemma, and neither is it implied by any of Schwartz’s results! We can see this via the following example.

**Example.** Let $S$ be a finite subset of $R$ containing 0, of size $s \geq 3$. Let $f = t_1 t_2 \in R[t_1, t_2]$. Then we have

$$|Z_{S^2}(f)| = 2s - 1.$$
DeMillo-Lipton-Zippel gives

$$|Z_{S^2}(f)| \leq s^2 - (s - 1)^2 = 2s - 1.$$  

Schwartz’s Theorem and the Schwartz-Zippel lemma gives

$$|Z_{S^2}(f)| \leq s^2 \left( \frac{1}{s} + \frac{1}{s} \right) = 2s = (\deg f)|S|.$$  

Thus neither Theorem 9.4.3 nor Theorem 9.4.1 imply Theorem 9.4.2. For the other direction, take $f = t_1 + t_2$. DeMillo-Lipton-Zippel gives $|Z_{S^2}(f)| \leq s^2 - (s - 1)^2 = 2s - 1$, while the other results give $|Z_{S^2}(f)| \leq s$.

But, we can still relate these results using our main result, the Generalized Alon-Füredi Theorem, by showing that both Theorem 9.4.1 and Theorem 9.4.2 follow from Theorem 9.1.2. In fact, we will prove general versions of these results over arbitrary rings.

**Theorem 9.4.4** (Generalized Schwartz-Zippel Lemma). Let $A = \prod_{i=1}^{n} A_i \subseteq R^n$ be a finite grid satisfying Condition (D), and suppose $|A_1| \geq \cdots \geq |A_n|$. Let $f \in R[t_1, \ldots, t_n]$ be a nonzero polynomial. Then

$$|Z_A(f)| \leq (\deg f) \prod_{i=1}^{n-1} |A_i|.$$  

*Proof.* If $\deg f \geq |A_n|$, then this holds trivially. So assume that $\deg f < |A_n|$. Then by Theorem 9.1.2, there are at least $m(|A_1|, \ldots, |A_n|; \sum_{i=1}^{n-1} |A_i| + |A_n| - \deg f)$ points of $A$ where $f$ is non-zero. This expression is equal to $|A_1| \cdots |A_{n-1}|(|A_n| - \deg f)$ by Lemma 9.2.1, and hence $f$ has at most $(\deg f) \prod_{i=1}^{n-1} |A_i|$ zeros in $A$. □

**Theorem 9.4.5** (Generalized DeMillo-Lipton-Zippel Theorem). Let $A = \prod_{i=1}^{n} A_i \subseteq R^n$ be a finite grid satisfying Condition (D), let $f \in R[t_1, \ldots, t_n]$ be a nonzero polynomial and for $i \in \{1, \ldots, n\}$ let $d_i = \deg_{t_i} f$. Assume that $0 \leq d_i < |A_i|$ for all $i \in \{1, \ldots, n\}$. Then

$$|Z_A(f)| \leq |A| - \prod_{i=1}^{n} (|A_i| - d_i).$$  

*Proof.* For $i \in \{1, \ldots, n\}$, put $a_i = |A_i|$ and $b_i = a_i - d_i$, so $1 \leq b_i \leq a_i$ for all $i$. Moreover $\deg f \leq \sum_{i=1}^{n} d_i$, so Theorem 9.1.2 gives

$$|U_A| \geq m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} a_i - \deg f) \geq m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} (a_i - d_i))$$

$$= m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} b_i) = \prod_{i=1}^{n} b_i = \prod_{i=1}^{n} (a_i - d_i).$$  

This proves the result as $|A| = |Z_A(f)| + |U_A(f)|$. □

*Remark.* (1) Using Corollary 8.1.4, one can easily adapt the original arguments of Theorems 9.4.1, 9.4.2 and 9.4.3 to prove their generalization over rings.

(2) A generalization of the Schwartz-Zippel Lemma over rings already appears in [6, Section 5] where the authors assume a stronger condition by taking subsets $S$ of $R$
such that $S$ is an integral domain in itself, and then considering the zeros of the polynomial in the grid $S^n$.

(3) The case of the Schwartz-Zippel Lemma in which $R = S = \mathbb{F}_q$ is due to Ore [114]. Thus the Schwartz-Zippel Lemma may be viewed as a “Restricted Variable Ore Theorem”.

9.5. Multiplicity Enhancements

That one can assign to a zero of a polynomial a positive integer called multiplicity is a familiar concept in the univariate case. The definition of the multiplicity $m(f, x)$ of a multivariate polynomial $f \in R[t]$ at a point $x \in R^n$ may be less familiar, but the concept is no less useful. All of the main results considered thus far are upper bounds on $|Z_A(f)|$, the number of zeros of a polynomial $f$ in a finite grid. By a multiplicity enhancement we mean the replacement of $|Z_A(f)|$ by $\sum_{x \in A} m(f, x)$ in such an upper bound. Here is the prototypical example: for a nonzero univariate polynomial $f$ over a field $F$ we have $\sum_{x \in F} m(f, x) \leq \deg f$.

Recently, multiplicity enhancements have become part of the polynomial method toolkit. In [78] Dvir, Kopparty, Saraf and Sudan gave a multiplicity enhancement of the Schwartz-Zippel Lemma. This was a true breakthrough with important applications in both combinatorics and theoretical computer science. In Section 9.4 we saw that the original work of Schwartz, DeMillo-Lipton and Zippel consists of more than the Schwartz-Zippel Lemma and gave some extensions of this work, in particular working over an arbitrary ring. So it is natural to consider multiplicity enhancements of these results. We do so here, giving a multiplicity enhancement of Theorem 9.4.3 over arbitrary rings $R$ and thus also of Theorem 9.4.4. On the other hand the Alon-Füredi Theorem does not allow for a multiplicity enhancement (at least not in the precise sense described above), as we will see in Example 9.5.4.

In places our treatment closely follows that of [78]. We need to set things up over a ring, whereas they work over a field which makes things a bit more involved. Nevertheless, their work carries over verbatim much of the time, and when this is the case we state the result in the form we need it, cite the analogous result in [78] and omit the proof.

9.5.1. Hasse Derivatives

Let $R[t] = R[t_1, \ldots, t_n]$. For $I = (i_1, \ldots, i_n) \in \mathbb{N}^n$, put $t^I = t_1^{i_1} \cdots t_n^{i_n}$ and $|I| = \sum_{j=1}^n i_j = \deg t^I$. Thus, $\{t^I\}_{I \in \mathbb{N}^n}$ is an $R$-basis for $R[t]$. For $I = (i_1, \ldots, i_n)$ and $J = (j_1, \ldots, j_n)$ in $\mathbb{N}^n$, we put

$${}\binom{I}{J} = \prod_{k=1}^n \binom{i_k}{j_k},$$

where $\binom{n}{k} = \frac{n!}{k!(n-k)!}$.
taking \( \binom{i}{j} = 0 \) if \( j > i \). We say that \( I \leq J \) if \( i_k \leq j_k \) for all \( k \). For \( J \in \mathbb{N}^n \), let \( D^J : R[t] \to R[t] \) be the unique \( R \)-linear map such that
\[
D^J(t^I) = \binom{I}{J} t^{I-J}.
\]
We have \( D^J(t^I) = 0 \), unless \( J \leq I \). Repeated application of the identity
\[
t^n = (t - x + x)^n = \sum_{j=0}^{n} \binom{n}{j} x^{n-j}(t-x)^j
\]
leads to the Taylor expansion: for \( f \in R[t] \) and \( x \in R^n \),
\[
f(t) = \sum_{J \in \mathbb{N}^n} D^J(f)(x)(t - x)^J.
\]
(9.1)
Applying the automorphism \( t \mapsto t + x \) gives the alternate form
\[
f(t + x) = \sum_{J \in \mathbb{N}^n} D^J(f)(x) t^J.
\]
These \( D^J(f) \) were defined in \[89\] and are now called Hasse derivatives.

**Proposition 9.5.1** ([78 Proposition 2.3]). Let \( f \in R[t] \), and let \( I, J \in \mathbb{N}^n \).

1. If \( f \) is homogeneous of degree \( d \), then \( D^I(f) \) is homogeneous of degree \( d - |I| \).
2. We have
\[
D^J(D^I(f)) = \binom{I+J}{I} D^{I+J}(f).
\]

**Lemma 9.5.2** (Leibniz’s Rule). Let \( f, g, h \in R[t] \) such that \( f = gh \). Then for \( i \in \mathbb{N} \), we have
\[
D^i(f) = \sum_{j=0}^{i} D^j(g)D^{i-j}(h).
\]
**Proof.** It suffices to show that \( D^i(t^m t^n) = \sum_{j=0}^{i} D^j(t^m)D^{i-j}(t^n) \). On the left hand side we have \( \binom{m+n}{i} t^{m+n-i} \), while on the right hand side we have \( \sum_{j=0}^{i} \binom{m}{j} \binom{n}{i-j} t^{m+n-i} \), which are equal by the Vandermonde’s identity for binomial coefficients. Alternately, look at the corresponding coefficients in \( f(t+x) \), and \( g(t+x)h(t+x) \). \( \square \)

### 9.5.2. Multiplicities

Let \( f \in R[t] \) be nonzero and \( x \in R^n \). The *multiplicity* of \( f \) at \( x \), denoted \( m(f, x) \), is the natural number \( m \) such that \( D^J(f)(x) = 0 \) for all \( J \) with \( |J| < m \) and \( D^J(f)(x) \neq 0 \) for some \( J \) with \( |J| = m \). We put \( m(0, x) = \infty \) for all \( x \in R^n \).

**Lemma 9.5.3** ([78 Lemma 2.4]). For \( f \in R[t] \), \( x \in R^n \) and \( I \in \mathbb{N}^n \), we have
\[
m(D^I(f), x) \geq m(f, x) - |I|.
\]
Given a vector $f = (f_1, \ldots, f_k) \in R[t]^k$, we put $m(f, x) = \min_{1 \leq j \leq k} m(f_j, x)$.

**Proposition 9.5.4** ([78, Proposition 2.5]). Let $X_1, \ldots, X_n, Y_1, \ldots, Y_\ell$ be independent indeterminates. Let $f = (f_1, \ldots, f_k) \in R[X_1, \ldots, X_n]^k$ and let $g = (g_1, \ldots, g_n) \in R[Y_1, \ldots, Y_\ell]^n$. We define $f \circ g \in R[Y_1, \ldots, Y_\ell]^k$ to be $f(g_1, \ldots, g_n)$.

1. For any $a \in R^\ell$ we have
   $$m(f \circ g, a) \geq m(f, g(a))m(g - g(a), a).$$

2. In particular, since $m(g - g(a), a) \geq 1$, we have
   $$m(f \circ g, a) \geq m(f, g(a)).$$

**Corollary 9.5.5** ([78, Corollary 2.6]). Let $f \in R[t]$ and let $a, b \in R^n$. Then for all $c \in R$ we have
   $$m(f(a + tb), c) \geq m(f, a + cb).$$

The following Lemma will help us generalize the fact that $\sum_{x \in F} m(f, x) \leq \deg f$ for $f \in F[t]$ to polynomials with coefficients in an arbitrary commutative rings with identity.

**Lemma 9.5.6.** Let $f, g, h \in R[t]$ be nonzero polynomials such that $f = gh$ and let $x \in R$. If $g(x)$ is not a zero divisor, then $m(f, x) = m(h, x)$.

**Proof.** For any nonnegative integer $i$, from Lemma 9.5.2 we have
   $$D^i(f) = D^0(g)D^i(h) + \cdots + D^i(g)D^0(h).$$

Therefore $m(f, x) \geq m(h, x)$, as we have $D^i(f)(x) = 0$ for all $i < m(h, x)$. Let $m := m(f, x) \geq 1$ (for $m = 0$ the result is easily proved). We now show that $D^i(h)(x) = 0$ for all $i < m$, thus proving $m(h, x) \geq m(f, x)$. For $i = 0$, we have $0 = f(x) = g(x)h(x)$, and since $g(x)$ is not a zero divisor, we must have $h(x) = D^0(h)(x) = 0$. Now $D^1(f)(x) = D^0(g)(x)D^1(h)(x) + D^1(g)(x)D^0(h)(x) = g(x)D^1(h)(x)$. Again, since $g(x)$ is not a zero divisor, $D^1(f)(x) = 0$ if and only if $D^1(h)(x) = 0$. Continuing in this way, at the $i$th step we have $D^j(h)(x) = 0$ for all $j < i$ and thus $D^i(f)(x) = g(x)D^i(h)(x)$. Since $g(x)$ is not a zero divisor and $i < m$, we see that $D^i(h)(x) = 0$.

**Lemma 9.5.7.** Let $R$ be a ring, and let $f \in R[t]$ be a polynomial of degree $d \geq 1$. Let $A = \{x_1, \ldots, x_n\} \subseteq R$ be a finite set satisfying Condition (D). Then
   $$\sum_{x \in A} m(f, x) \leq d.$$

**Proof.** We have $(t - x_i)^{m(f, x_i)} \mid f$ for all $i \in \{1, \ldots, n\}$. In particular we may write
   $$f(t) = (t - x_1)^{m(f, x_1)}g_1(t),$$

so $\deg f \geq m(f, x_1)$ and we are done if $n = 1$. So suppose $n \geq 2$. Since $A$ satisfies Condition (D), the element $(x_n - x_1)^{m(f, x_1)} \cdots (x_n - x_{n-1})^{m(f, x_{n-1})}$ of $R$ is not a zero divisor. Therefore, if we have $f(t) = (\prod_{i=1}^{n-1}(t - x_i)^{m(f, x_i)})g_{n-1}(t)$, then $m(f, x_n) = m(g_{n-1}, x)$ by Lemma 9.5.6 and hence $(t - x_n)^{m(f, x_n)} \mid g_{n-1}(t)$. Thus by induction we get $\prod_{i=1}^{n}(t - x_i)^{m(f, x_i)} \mid f(t)$, which implies that $\sum_{x \in A} m(f, x) \leq \deg f$.
From the proof of the multiplicity enhanced Schwartz-Zippel Lemma in [78], we extract the following lemma.

**Lemma 9.5.8** (DKSS Lemma). Let \( A = \prod_{i=1}^{n} A_i \subseteq \mathbb{R}^n \) be a finite subset satisfying Condition (D). Let \( f \in \mathbb{R}[t] \), and write
\[
f = \sum_{j=0}^{d_n} f_j(t_1, \ldots, t_{n-1}) t_n^j
\]
with \( f_{d_n} \neq 0 \). Put \( A' = \prod_{i=1}^{n-1} A_i \). For all \( x' = (x_1, \ldots, x_{n-1}) \in A' \), we have
\[
\sum_{x \in A_n} m(f, (x', x)) \leq |A_n| m(f_{d_n}, x') + d_n.
\]

**Proof.** Fix an \( x' \in A' \). Choose \( I' \in \mathbb{N}^{n-1} \) such that \(|I'| = m(f_{d_n}, x')\) and \( D^{I'}(f_{d_n})(x') \neq 0 \). Put \( I = I' \times \{0\} \in \mathbb{N}^n \). Then
\[
D^I(f) = \sum_{j=0}^{d_n} D^{I'}(f_j)t_n^j,
\]
so \( D^I(f) \neq 0 \). By Lemma 9.5.3 we have
\[
m(f, (x', x)) \leq |I| + m(D^I(f), (x', x)) = m(f_{d_n}, x') + m(D^I(f), (x', x)).
\]
Applying Corollary 9.5.5 to \( D^I(f) \) with \( a = (x', 0) \), \( b = (0, 1) \) and \( c = x \) we get
\[
m(D^I(f), (x', x)) \leq m(D^I(f)(x', t_n), x).
\]
Summing over \( x \in A_n \) gives
\[
\sum_{x \in A_n} m(f, (x', x)) \leq |A_n| m(f_{d_n}, x') + \sum_{x \in A_n} m(D^I(f)(x', t_n), x).
\]
Since \( I = I' \times \{0\} \), \( D^I(f)(x', t_n) \) has degree \( d_n \) and thus Lemma 9.5.7 gives
\[
\sum_{x \in A_n} m(D^I(f)(x', t_n), x) \leq d_n.
\]
The result follows. \( \square \)

### 9.5.3. Multiplicity Enhanced Theorems

**Theorem 9.5.9** (Multiplicity Enhanced Schwartz Theorem). Let \( R \) be a ring, let \( A = \prod_{i=1}^{n} A_i \subseteq \mathbb{R}^n \) be finite, nonempty and satisfy Condition (D), and let \( f = f_n \in F[t_1, \ldots, t_n] \) be a nonzero polynomial. Let \( d_n = \deg_{t_n} f \), and let \( f_{n-1} \in R[t_1, \ldots, t_{n-1}] \) be the coefficient of \( t_n^{d_n} \) in \( f_n \). Let \( d_{n-1} = \deg_{t_{n-1}} f_{n-1} \), and let \( f_{n-2} \in R[t_1, \ldots, t_{n-2}] \) be the coefficient of \( t_{n-2}^{d_{n-2}} \) in \( f_{n-2} \). Continuing in this manner we define for all \( 1 \leq i \leq n \) a polynomial...
$f_i \in \mathbb{R}[t_1, \ldots, t_n]$ with $\deg_{t_i} f_i = d_i$. Then

$$\sum_{x \in A} m(f, x) \leq |A| \sum_{i=1}^{n} \frac{d_i}{|A_i|}.$$  

**Proof.** We prove this by induction on $n$. The case $n = 1$ is Lemma 9.5.7. Suppose the result holds for polynomials in $n-1$ variables. Let $A' = \prod_{i=1}^{n-1} A_i$. Applying Lemma 9.5.8 and then the induction hypothesis, we get

$$\sum_{x \in A} m(f, x) = \sum_{x' \in A'} \sum_{x \in A_n} m(f, (x', x)) \leq |A_n| \sum_{x' \in A'} m(f_{n-1}, x') + |A'| d_n$$

$$\leq |A_n||A'| \sum_{i=1}^{n-1} \frac{d_i}{|A_i|} + |A| \frac{d_n}{|A_n|} = |A| \sum_{i=1}^{n} \frac{d_i}{|A_i|}.$$  

\[Q.E.D.\]

**Theorem 9.5.10** (Multiplicity Enhanced Schwartz-Zippel Lemma). Let $A = \prod_{i=1}^{n} A_i \subseteq \mathbb{R}^n$ be a finite grid satisfying Condition (D), and suppose $|A_1| \geq \cdots \geq |A_n|$. Let $f \in \mathbb{R}[t_1, \ldots, t_n]$ be a nonzero polynomial. Then

$$\sum_{x \in A} m(f, x) \leq (\deg f) \prod_{i=1}^{n} |A_i|.$$  

**Proof.** Define $d_i$'s and $f_i$'s as in Theorem 9.5.9. Then the coefficient of $t_1^{d_1} \cdots t_n^{d_n}$ is non-zero in $f$, and hence $\sum_{i=1}^{n} d_i \leq \deg f$. Thus we have

$$\sum_{x \in A} m(f, x) \leq |A| \sum_{i=1}^{n} \frac{d_i}{|A_i|} \leq |A_1| \cdots |A_{n-1}| \sum_{i=1}^{n} d_i \leq (\deg f) \prod_{i=1}^{n-1} |A_i|.$$  

\[Q.E.D.\]

**Remark.** (1) When $R$ is a field, Theorem 9.5.9 was proved by Geil and Thomsen [84, Theorem 5]. They also build closely on [78].

(2) Unlike most of the other results presented here, Theorem 9.5.9 is not claimed to be sharp in all cases. In fact, it is not always sharp, and Geil and Thomsen give significant discussion of this point including an algorithm which sometimes leads to an improved bound [84, Theorem 6] and further numerical exploration.

(3) When $R$ is a field and $A_1 = \cdots = A_n$, then Theorem 9.5.10 appears as Lemma 2.7 in [78].

### 9.5.4. A Counterexample

It is natural to ask whether Alon-Füredi holds in multiplicity enhanced form, i.e., whether the bound

$$|Z_A(f)| \leq |A| - m(|A_1|, \ldots, |A_n|; \sum_{i=1}^{n} |A_i| - \deg f)$$
could be improved to

$$\sum_{x \in A} m(f, x) \leq |A| - \mathbf{m}(|A_1|, \ldots, |A_n|; \sum_{i=1}^n |A_i| - \deg f),$$

in Theorem 9.1.1. The following example shows that such an improvement does not always hold.

**Example.** Let $n = 2$ and let $S = A_1 = A_2$ be a finite subset of $s$ elements in $R$ which contains 0, and put $A = S \times S$. Let $d_1, d_2 \in \mathbb{Z}^+$ be such that $d_1, d_2 < s \leq d_1 + d_2$. Then $f = t_1^{d_1} t_2^{d_2}$ is $A$-reduced, and we have $\mathbf{m}(s, s; 2s - d_1 - d_2) = 2s - d_1 - d_2 - 1$ (by the greedy distribution). But

$$\sum_{x \in A} m(f, x) = s(d_1 + d_2) > s^2 - 2s + d_1 + d_2 + 1 = s^2 - \mathbf{m}(s, s; 2s - d_1 - d_2),$$

since $(s - 1)(d_1 + d_2) > (s - 1)^2$ (we have assumed $d_1 + d_2 > s - 1$) and thus the multiplicity enhanced version of Alon-Füredi would not hold in this case.

**Remark.** Since $s(d_1 + d_2) > s(d_1 + d_2) - d_1 d_2 = s^2 - (s - d_1)(s - d_2)$, we can use the polynomial $t_1^{d_1} t_2^{d_2}$ for any $d_1, d_2 < s$ to show that the multiplicity enhanced version of DeMillo-Lipton-Zippel Theorem (see Theorem 9.4.5) does not hold in all cases either.

### 9.6. Connections with Coding Theory

A $q$-ary linear code of length $n$ is simply a subspace $C$ of $\mathbb{F}_q^n$. The most important parameter of a code is the **Hamming distance** $d(C) = \min\{d(x, y) \mid x, y \in C, x \neq y\}$ where $d(x, y)$ for $x = (x_1, \ldots, x_n), y = (y_1, \ldots, y_n) \in \mathbb{F}_q^n$ is equal to $|\{i \in \{1, \ldots, n\} \mid x_i \neq y_i\}|$. For linear codes $d(C)$ is simply equal to $\min\{w(x) \mid x \in C\}$ where $w(x) = d(x, 0)$ is the Hamming weight of $x$. These notions can be defined over arbitrary fields $F$ and rings $R$ as well. We refer to [104] for more background on Coding Theory. In this section we will see how the Alon-Füredi Theorem and its generalization are essentially statements that give the Hamming distance of certain linear codes.

Over the finite field $\mathbb{F}_q$, we can consider the whole space $\mathbb{F}_q^n$ as a finite grid. Then the set of reduced polynomials with respect to this grid (see Chapter 8) are simply called reduced polynomials. We denote the set of reduced polynomials by $\mathcal{P}(n, q)$; it is an $\mathbb{F}_q$-vector space of dimension $q^n$. The evaluation map gives an $\mathbb{F}_q$-linear isomorphism

$$E : \mathcal{P}(n, q) \rightarrow \mathbb{F}_q^{p^n}, \ f \mapsto (x \in \mathbb{F}_q^n \mapsto f(x)).$$

Fixing an ordering $\alpha_1, \ldots, \alpha_{q^n}$ of $\mathbb{F}_q^n$, this isomorphism allows us to identify each $f \in \mathcal{P}(n, q)$ with its value table $(f(\alpha_1), \ldots, f(\alpha_{q^n}))$. For $d \in \mathbb{N}$ we denote by $\mathcal{P}_d(n, q)$ the set of all reduced polynomials of degree at most $d$. The dimension of $\mathcal{P}_d(n, q)$ is equal to the number of integer solutions to $e_1 + \cdots + e_n \leq d$, $e_1, \ldots, e_n \geq 0$. The evaluation map restricted to $\mathcal{P}_d(n, q)$ also gives an injective $\mathbb{F}_q$-linear map.

**Definition.** The set of all value tables of all polynomials in $\mathcal{P}_d(n, q)$ is called the $d$-th order generalized Reed-Muller code of length $q^n$, denoted by $\text{GRM}_d(n, q)$.
For $q = 2$, these codes were introduced and studied by Muller [111] and Reed [118]. These were generalized to arbitrary $q$ by Kasami, Lin and Peterson [97] who also gave an explicit formula for the minimum distance of the generalized Reed-Muller codes. A systematic study of these codes in terms of the polynomial formulation was conducted by Delsarte, Goethals and MacWilliams in [71], where they also classified all the minimum weight codewords. We will prove the result of Kasami, Lin and Peterson [97, Theorem 5] using the Alon-Füredi Theorem, thus giving shorter and more elementary proof than the original. While (binary) Reed-Muller codes are mentioned by Alon and Füredi in [3] under Corollary 1, the connection between [3, Theorem 5] and generalized Reed-Muller codes is not explored.

**Theorem 9.6.1** (Kasami-Lin-Peterson). The minimum weight of the $d$-th order Generalized Reed-Muller code $GRM_d(n, q)$ is equal to $(q - b)q^{n-a-1}$ where $d = a(q - 1) + b$ with $0 < b \leq q - 1$.

**Proof.** The minimum weight of $GRM_d(n, q)$ is equal to the least number of nonzero values taken by a nonzero reduced polynomial of degree at most $d$, which by Alon-Füredi and its sharpness is equal to $m(q, \ldots, q; nq - d)$. Moreover we have

$$(nq - d) - n = n(q - 1) - a(q - 1) - b = (n - a - 1)(q - 1) + q - 1 - b,$$

and

$$0 \leq q - 1 - b < q - 1,$$

so by Lemma 9.2.1 we have

$$m(q, \ldots, q; nq - d) = (q - b)q^{n-a-1}.$$  

The Generalized Alon-Füredi Theorem can also be stated in terms of coding theory. Let $A = \prod_{i=1}^{n} A_i$ be a finite grid in $R^n$ satisfying Condition (D), with $a_i = |A_i|$ for $i \in \{1, \ldots, n\}$. Given positive integers $b_i \leq a_i$ for all $i \in \{1, \ldots, n\}$, and a natural number $d \leq \sum_{i=1}^{n} (a_i - b_i)$, we define the *generalized affine grid code* $GAGC_d(A; b_1, \ldots, b_n)$ as the set of value tables of all polynomials $f \in R[t]$ with $\deg_t f \leq a_i - b_i$ for all $i$ and $\deg f \leq d$ evaluated on $A$. We put

$$AGC_d(A) = GAGC_d(A; 1, \ldots, 1)$$

and speak of *affine grid codes*. Then from Theorem 9.1.2 (similar to Theorem 9.6.1) it follows that:

**Theorem 9.6.2.** The minimum weight of $GAGC_d(A; b_1, \ldots, b_n)$ is $m(a_1, \ldots, a_n; b_1, \ldots, b_n; \sum_{i=1}^{n} a_i - d)$.

Affine grid codes were studied in [107] under the name of Affine Cartesian Codes, where they proved the following:

**Theorem 9.6.3** ([107, Thm. 3.8]). Let $F$ be a field and $A = \prod_{i=1}^{n} A_i \subseteq F^n$ a finite grid with $|A_1| \geq \cdots \geq |A_n| \geq 1$. Then the minimum weight of $AGC_d(A)$ is

$$\begin{cases} |A_1| \cdots |A_{k-1}|(|A_k| - \ell) & \text{if } d \leq \sum_{i=1}^{n} (|A_i| - 1) - 1, \\ 1 & \text{if } d \geq \sum_{i=1}^{n} (|A_i| - 1), \end{cases}$$

Page 129
Thus \( f \) and let \( H \) can identify the points of \( S \), and by Theorem 9.7.1 instead of the approach used in [3].

Füredi, which is part (3) of the following theorem. However, our proof is via Theorem 9.6.3 is self-contained and thus gives a proof of Alon-Füredi with the balls in bins constant replaced by its explicit value \( P(y_G) \). On the other hand it is longer than the other proofs of Alon-Füredi appearing in the literature.

(1) When \( b_1 \geq \cdots \geq b_n \), the greedy algorithm computes \( m(a_1, \ldots, a_n; b_1, \ldots, b_n; N) \) and we could give a similarly explicit description of \( GAGC_d(A_1; b_1, \ldots, b_n) \).

9.7. Blocking Sets and Hyperplane Coverings

9.7.1. Partial Coverings of Grids by Hyperplanes

By a hyperplane in \( R^n \) we mean a polynomial \( H = c_1 t_1 + \cdots + c_n t_n + r \in R[\mathbb{T}] \) for which at least one \( c_i \) is not a zero-divisor. (Referring to the polynomial itself rather than its zero locus in \( R^n \) will make the discussion cleaner.) A family \( \mathcal{H} = \{H_i\}_{i=1}^d \) covers \( x \in R^n \) if \( H_i(x) = 0 \) for some \( i \in \{1, \ldots, n\} \); \( \mathcal{H} \) covers a subset \( S \subseteq R^n \) if it covers every point of \( S \), and \( \mathcal{H} \) partially covers \( S \) otherwise. For a family \( \mathcal{H} = \{H_i\}_{i=1}^d \) of hyperplane in \( R^n \), put

\[
   f_{\mathcal{H}} = \prod_{i=1}^d H_i.
\]

Thus \( f_{\mathcal{H}} \in R[t_1, \ldots, t_n] \) is a polynomial of degree \( d \). Clearly, if \( \mathcal{H} \) covers a point \( x \), then \( f_{\mathcal{H}}(x) = 0 \). When \( R \) is an integral domain, the converse also holds, and then we can identify the points of \( R^n \) covered by \( \mathcal{H} \) with the zeros of the polynomial \( f_{\mathcal{H}} \) that has degree \( |\mathcal{H}| \). We now revisit the original combinatorial problem studied by Alon and Füredi, which is part (3) of the following theorem. However, our proof is via Theorem 9.1.1 instead of the approach used in [3].

Theorem 9.7.1. Let \( R \) be an integral domain, let \( A = \prod_{i=1}^n A_i \subseteq R^n \) be a finite grid, and let \( \mathcal{H} = \{H_i\}_{i=1}^d \) be family of hyperplanes in \( R^n \).

(1) If \( \mathcal{H} \) partially covers \( A \), then \( \mathcal{H} \) fails to cover at least \( m(|A_1|, \ldots, |A_n|; \sum_{i=1}^n |A_i| - d) \) points of \( A \).

(2) For all \( d \in \mathbb{Z}^+ \), there is a family of hyperplane \( \{H_1, \ldots, H_d\} \) where each \( H_i \) is of the form \( t_j - x_i \) for some \( j_i \in \{1, \ldots, n\} \) and \( x_i \in A_{j_i} \) such that this family covers all but exactly \( m(|A_1|, \ldots, |A_n|; \sum_{i=1}^n |A_i| - d) \) points of \( A \).

(3) If \( \mathcal{H} \) covers all but exactly one point of \( A \), then \( d \geq \sum_{i=1}^n (|A_i| - 1) \).
Proof. (1) As above, \( \mathcal{H} \) covers \( x \in \mathbb{R}^n \) iff \( f_{\mathcal{H}}(x) = 0 \). Now apply the Alon-F"uredi Theorem to \( f_{\mathcal{H}} \).

(2) The sharpness construction of Section [9.3.1] is precisely of this form.

(3) Say \( \mathcal{H} \) covers all points of \( A \) except one. Then

\[
1 = \bigcup A(f_{\mathcal{H}}) \geq \mathfrak{m}(|A_1|, \ldots, |A_n|; \sum_{i=1}^n |A_i| - d).
\]

Now if \( d < \sum_{i=1}^n (|A_i| - 1) \), then \( \sum_{i=1}^n |A_i| - d \geq n + 1 \), and since \( \mathfrak{m}(|A_1|, \ldots, |A_n|; n + 1) = 2 \), we get a contradiction by using Lemma 9.2.3.

\[ \square \]

Remark. (1) The proof of Theorem 9.7.1(3) can clearly be adapted to any polynomial of degree \( d \) which vanishes on all points of the grid except one. In this manner we get an alternate proof of Lemma 8.2.1 using the Alon-F"uredi theorem.

(2) Let \( R = \mathbb{Z}/4\mathbb{Z} \). Then we have a family of 5 lines in \( \mathbb{R}^2 \) which cover all points of \( \mathbb{R}^2 \) except the origin, given by \( \mathcal{H} = \{ t_1 - 1, t_1 - 2, t_1 - 3, t_2 - 2, t_1 + 2t_2 - 2 \} \). Therefore, Theorem 9.7.1 need not be true when \( R \) is not an integral domain. In fact, this example can be generalized to show that Theorem 9.7.1 does not hold for any finite grid \( A \) in \( \mathbb{R}^n \) which does not satisfy Condition (D). When \( A \) does satisfy Condition (D), and \( R \) is not an integral domain, we do not know if the result is true.

We complement Theorem 9.7.1 by computing the minimum cardinality of a hyperplane covering of a finite grid (not necessarily satisfying Condition (D)) over a ring \( R \).

**Theorem 9.7.2.** Let \( A = \prod_{i=1}^n A_i \subseteq \mathbb{R}^n \) be a finite grid, and let \( \mathcal{H} = \{ H_i \}_{i=1}^d \) be a hyperplane covering of \( A \). Then \( d \geq \min \{|A_i| \mid i \in \{1, \ldots, n\} \} \).

**Proof.** First we observe that if \( A \) satisfies Condition (D) then the result is almost immediate: going by contraposition, if \( d \leq |A_i| - 1 \) for all \( i \in \{1, \ldots, n\} \) then \( f_{\mathcal{H}} \) is nonzero and \( A \)-reduced, so it cannot vanish identically on \( A \) by Lemma 8.1.5. Now we give a non-polynomial method proof in the general case. Without loss of generality assume \( |A_1| \geq \cdots \geq |A_n| \). We claim that any hyperplane \( H = \sum_{i=1}^n c_i t_i + g \) covers at most \( \prod_{i=1}^{n-1} |A_i| \) points of \( A \): this suffices, for then \( d \geq |A_n| \).

**Proof of claim:** Fix \( i \in \{1, \ldots, n\} \) such that \( c_i \) is not a zero-divisor in \( R \). Let \( \pi : \mathbb{R}^n \to \mathbb{R}^{n-1} \) be the projection \((x_1, \ldots, x_n) \mapsto (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)\). Then

\[
A = \bigcap_{x'=(x_1,\ldots,x_{i-1},x_{i+1},\ldots,x_n)\in \pi(A)} \{x_1\} \times \cdots \times \{x_{i-1}\} \times A_i \times \{x_{i+1}\} \times \cdots \{x_n\}
\]

is a partition of \( A \) into \( |\pi(A)| = \prod_{j \neq i} |A_j| \) nonempty subsets, each one of which meets \( H \) in at most one point since \( c_i \) is not a zero divisor. So

\[
|Z(H \cap A)| \leq \prod_{j \neq i} |A_j| \leq \prod_{i=1}^{n-1} |A_i|.
\]

\[ \square \]
Conjecture 9.7.3. Let \( R \) be a ring, and let \( A_1, \ldots, A_n \subseteq R \) be nonempty (but possibly infinite). Let \( H = \{ H_j \}_{j \in J} \) be a covering of the grid \( A = \prod_{i=1}^{n} A_i \) by hyperplanes. Then \( |J| \geq \min \{|A_i| \mid i \in J\} \).

Remark. (1) For \( i \in \{1, \ldots, n\} \), let \( B_i \subseteq A_i \subseteq R \). Then we need at least as many hyperplanes to cover \( \prod_{i=1}^{n} A_i \) as we do to cover \( \prod_{i=1}^{n} B_i \). Together with Theorem 9.7.2 it follows that in the setting of Conjecture 9.7.3 we need at least \( \min(|A_i|, \aleph_0) \) hyperplanes, since if \( A \) is infinite then for every finite subgrid \( B = B_1 \times \cdots \times B_n \) of \( A \) we need at least \( \min\{|B_i|\} \) hyperplanes to cover it. Thus Conjecture 9.7.3 holds when \( R \) is countable.

(2) When \( R \) is a field and \( A = R^n \), Conjecture 9.7.3 is a case of [48, Theorem 3].

9.7.2. Partial Covers and Blocking Sets in Finite Geometries

The same ideas can be used to prove old and new results about projective and affine spaces over finite fields.

Let \( \text{PG}(n, q) \) denote the \( n \)-dimensional projective space over \( \mathbb{F}_q \) and let \( \text{AG}(n, q) \) denote the \( n \)-dimensional affine space over \( \mathbb{F}_q \). The set \( \text{AG}(n, q) \) comes equipped with a sharply transitive action of the additive group of \( \mathbb{F}_q^n \) and thus a choice of a point \( x \in \text{AG}(n, q) \) induces an isomorphism \( \text{AG}(n, q) \cong \mathbb{F}_q^n \). We will make such identifications without further comment.

A partial cover of \( \text{PG}(n, q) \) is a set of hyperplanes that do not cover all the points. The points missed by a partial cover are called holes.

Theorem 9.7.4. Let \( \mathcal{H} \) be a partial cover of \( \text{PG}(n, q) \) of size \( k \in \mathbb{Z}^+ \). Then \( \mathcal{H} \) has at least \( m(q, \ldots, q; nq - k + 1) \) holes.

Proof. Let \( H \in \mathcal{H} \). Then \( \text{PG}(n, q) \setminus H \cong \text{AG}(n, q) \) so \( \mathcal{H} \setminus H \) is a partial cover of \( \mathbb{F}_q^n \) by \( k - 1 \) hyperplanes. As in Theorem 9.7.1, there are at least \( m(q, \ldots, q; nq - (k - 1)) \) points not covered by \( \mathcal{H} \). \( \square \)

Corollary 9.7.5. If \( 0 \leq a < q \), a partial cover of \( \text{PG}(n, q) \) of size \( q + a \) has at least \( q^{n-1} - aq^{n-2} \) holes.

Proof. By Theorem 9.7.4 there are at least \( m(q, \ldots, q; (n - 1)q - a + 1) \) holes. Since \( 0 \leq a < q \), the greedy distribution is \( (q, \ldots, q, q - a, 1) \), and the result follows. \( \square \)

Dodunekov, Storme and Van de Voorde have shown that a partial cover of \( \text{PG}(n, q) \) of size \( q + a \) has at least \( q^{n-1} - aq^{n-2} \) holes if \( 0 \leq a < \frac{q - 2}{3} \) [75, Theorem 17]. Corollary 9.7.5 gives an improvement in that the restriction on \( a \) is relaxed. They also show that if \( a < \frac{q - 2}{3} \) and the number of holes are at most \( q^{n-1} \), then they are all contained in a single hyperplane. We cannot make any such conclusions from our arguments.

Projective duality yields a dual form of Theorem 9.7.4: \( k \) points in \( \text{PG}(n, q) \) which do not meet all hyperplanes must miss at least \( m(q, \ldots, q; nq - k + 1) \) of them. Thus:

Theorem 9.7.6. Let \( S \) be a set of \( k \) points in \( \text{AG}(n, q) \). Then there are at least \( m(q, \ldots, q; nq - k + 1) - 1 \) hyperplanes of \( \text{AG}(n, q) \) which do not meet \( S \).
Proof. Add a hyperplane at infinity to get to the setting of PG(n, q) and then apply the dual form of Theorem 9.7.4.

The general problem of the number of linear subspaces missed by a given set of points in PG(n, q) is studied by Metsch in [109]. We wish to note that Theorem 9.7.6 gives the same bounds as Part a) of [109, Theorem 1.2] for the specific case when the linear subspaces are hyperplanes.

A blocking set in AG(n, q) or PG(n, q) is a set of points that meets every hyperplane. The union of the coordinate axes in \( \mathbb{F}_q^n \) yields a blocking set in AG(n, q) of size \( n(q - 1) + 1 \). Doyen conjectured in a 1976 Oberwolfach lecture that \( n(q - 1) + 1 \) is the least possible size of a blocking set in AG(n, q). A year later Jamison [93] proved this conjecture, and then an alternate (and simpler) proof by Brouwer and Schrijver [37] was found. We are in a position to give another proof.

Corollary 9.7.7 (Jamison-Brouwer-Schrijver). The minimum size of a blocking set in AG(n, q) is \( n(q - 1) + 1 \).

Proof. Let \( B \subseteq AG(n, q) \) be a blocking set of cardinality at most \( n(q - 1) \). By Theorem 9.7.6, Lemma 9.2.1 and Lemma 9.2.3, there are at least

\[
m(q, \ldots, q; nq - n(q - 1) + 1) - 1 = m(q, \ldots, q; n + 1) - 1 = 1
\]

hyperplanes which do not meet \( B \).

Turning now to PG(n, q), every line is a blocking set. But classifying blocking sets that do not contain any line is one of the major open problems in finite geometry. For a survey on blocking sets in finite projective spaces, see [55, Chapter 3].

If \( B \subseteq PG(n, q) \), \( x \in B \) and \( H \) is a hyperplane in PG(n, q), then \( H \) is a tangent to \( B \) through \( x \) if \( H \cap B = \{x\} \). An essential point of a blocking set \( B \) in PG(n, q) is a point \( x \) such that \( B \setminus \{x\} \) is not a blocking set. A point \( x \) of \( B \) is essential if and only if there is a tangent hyperplane to \( B \) through \( x \).

Theorem 9.7.8. Let \( B \) be a blocking set in PG(n, q) and \( x \) an essential point of \( B \). There are at least \( m(q, \ldots, q; nq - |B| + 2) \) tangent hyperplanes to \( B \) through \( x \).

Proof. Let \( H \) be a tangent hyperplane to \( B \) through \( x \). Then \( B' = B \setminus \{x\} \subseteq PG(n, q) \setminus H \cong AG(n, q) \). By Theorem 9.7.6 there are at least \( m(q, \ldots, q; nq - |B| + 2) - 1 \) hyperplanes in AG(n, q) that do not meet \( B' \). Since \( B \) is a blocking set all of these hyperplanes, when seen in PG(n, q), must meet \( x \). Thus there are at least \( m(q, \ldots, q; nq - |B| + 2) \) tangent hyperplanes to \( B \) through \( x \).

Corollary 9.7.9 (Blokhuis-Brouwer [26]). Let \( B \) be a blocking set in PG(2, q) of size \( 2q - s \). There are at least \( s + 1 \) tangent lines through each essential point of \( B \).

Proof. By Theorem 9.7.8, each essential point of \( B \) has at least

\[
m(q, q; 2q - (2q - s) + 2) = m(q, q; s + 2)
\]

tangent lines. Since \( |B| = 2q - s < q^2 + q + 1 = |PG(2, q)| \), there exists \( x \in PG(2, q) \setminus B \). There are \( q + 1 \) lines through \( x \), so \( 2q - s = |B| \geq q + 1 \). Thus \( s + 1 \leq q \), so the greedy distribution is \( (s + 1, 1) \) and \( m(q, q; s + 2) = s + 1 \).
Corollary 9.7.10 ([75, Theorem 7]). If $0 \leq a < q$, there are at least $q^{n-1} - aq^{n-2}$ tangent hyperplanes through each essential point of a blocking set of size $q + a + 1$ in $\text{PG}(n, q)$.

Proof. By Theorem 9.7.8 and the proof of Corollary 9.7.5, each essential point of $B$ has at least $m(q, \ldots, q; nq - (q + a + 1) + 2) = q^{n-1} - aq^{n-2}$ tangent hyperplanes. □
A. Nederlandstalige samenvatting

Deze thesis bestaat uit twee delen. In het eerste deel van de thesis werd de theorie van valuaties van schier veelhoeken, in combinatie met computerberekeningen (in GAP en SageMath), gebruikt om enerzijds nieuwe schier achthoeken te construeren en te bestuderen en anderzijds om karakterisatieresultaten te bekomen van schier veelhoeken in termen van bepaalde deelmeetkunden. In het tweede deel van de thesis wordt er dieper ingegaan op de polynomiale methode die toelaat om via allerhande manipulaties van polynomen bepaalde interessante resultaten uit de getallenleer, combinatoriek, eindige meetkunde, ... te bewijzen.

A.1. Deel 1 (Hoofdstukken 1 t.e.m. 6)

Een **schier veelhoek** is een punt-rechte meetkunde $S$ die aan de volgende eigenschappen voldoet:

- Elke twee verschillende punten zijn bevat in tenhoogste één rechte.
- De collineariteitsgraad $\Gamma$ van $S$ heeft eindige diameter.
- Voor elk punt $x$ en elke rechte $L$ bestaat er een uniek punt op $L$ dat het dichtst bij $x$ gelegen is met betrekking tot de afstand in $\Gamma$.

Ingeval $d$ de diameter van $\Gamma$ is, wordt de schier veelhoek ook een **schier $2d$-hoek** genoemd. Een schier veelhoek heeft *orde* $(s,t)$ als elke rechte precies $s+1$ punten bevat, en als elk punt bevat is in precies $t+1$ rechten. Een schier $2d$-hoek met $d \geq 2$ wordt een **veralgemeende $2d$-hoek** genoemd als de volgende additionele eigenschappen voldaan zijn:

- Elk punt is incident met tenminste twee rechten.
- Als $x$ en $y$ twee punten zijn op afstand $i \in \{1,2,\ldots,d-1\}$, dan heeft $y$ een unieke buur die op afstand $i-1$ van $x$ gelegen is.

In het eerste deel van de thesis wordt veelvuldig gebruik gemaakt van volgende schier veelhoeken.

- $H(q,1)$ stelt de veralgemeende zeshoek van orde $(q,1)$ voor die afkomstig is van het Desarguesiaans projectief vlak PG(2, $q$),
- $H(q)$ stelt de split Cayley veralgemeende zeshoek van orde $(q,q)$ voor.
- $H(q)^D$ stelt de punt-rechte duaal van $H(q)$ voor.
- $T(q,q^2)$ stelt de duale twisted triality hexagon van orde $(q,q^2)$ voor.
- HJ stelt de Hall-Janko schier achthoek voor die geconstrueerd werd door Cohen [52].
Constructies van bovenvermelde veralgemeende zeshoeken kunnen gevonden worden in het boek [138].

Eén van de hoofdresultaten uit de thesis is de constructie in Hoofdstuk 5 van twee nieuwe schier achthoeken die een grote automorfismegroep hebben.

**Theorem A.1.1.** (a) Noem $O_1$ de punt-rechte meetkunde waarvan de punten de 4095 centrale involuties van de groep $G_1 := G_2(4):2$ zijn en waarvan de rechten alle triples $\{x, y, xy\}$ zijn, waarbij $x$ en $y$ twee commuterende centrale involuties van $G_2(4):2$ zijn waarvoor $[G_1 : N_{G_1}(\langle x, y \rangle)] \in \{1365, 13650\}$. Dan is $O_1$ een schier achthoek van orde $(2, 10)$.

(b) Noem $S_1$ de verzameling van alle rechten $\{x, y, z\}$ waarbij $x$ en $y$ twee commuterende involuties van $G_1 = G_2(4):2$ zijn waarvoor $[G_1 : N_{G_1}(\langle x, y \rangle)] = 1365$. Dan is $S_1$ een rechtenspread van $O_1$. Als $Q_1$ de verzameling van alle quads van $O_1$ is, dan is de punt-rechte meetkunde $H_1$ met puntenverzameling $S_1$ en rechtenverzameling $Q_1$ een veralgemeende zeshoek die isomorf is met de duale split Cayley hexagon $H(4)^D$, als we voor incidentie “het bevat zijn in” nemen.

(c) De automorfismegroep van $O_1$ is isomorf met $G_2(4):2$. De automorfismen van $O_1$ zijn precies de toevoegingen met elementen van $G_2(4):2$.

**Theorem A.1.2.** (a) Noem $O_2$ de punt-rechte meetkunde waarvan de punten de 315 centrale involuties van de groep $G_2 := L_3(4):2^2$ zijn en waarvan de rechten alle triples $\{x, y, xy\}$ zijn, waarbij $x$ en $y$ twee commuterende centrale involuties van $L_3(4):2^2$ zijn waarvoor $[G_2 : N_{G_2}(\langle x, y \rangle)] \in \{105, 420\}$. Dan is $O_2$ een schier achthoek van orde $(2, 4)$.

(b) Noem $S_2$ de verzameling van alle rechten $\{x, y, z\}$ waarbij $x$ en $y$ twee commuterende involuties van $G_2 = G_2(4):2$ zijn waarvoor $[G_2 : N_{G_2}(\langle x, y \rangle)] = 105$. Dan is $S_2$ een rechtenspread van $O_2$. Als $Q_2$ de verzameling van alle quads van $O_2$ is, dan is de punt-rechte meetkunde $H_2$ met puntenverzameling $S_2$ en rechtenverzameling $Q_2$ een veralgemeende zeshoek van orde $(4, 1)$, als we voor incidentie “het bevat zijn in” nemen.

(c) De automorfismegroep van $O_2$ is isomorf met $L_3(4):2^2$. De automorfismen van $O_2$ zijn precies the toevoegingen met elementen van $L_3(4):2^2$.

De schier achthoeken $O_1$ en $O_2$ worden de $G_2(4)$ en $L_3(4)$ schier achthoeken genoemd. In de thesis werd eveneens aangetoond dat $O_2$ ingebak kan worden in $O_1$ als een volle deelmeetkunde. Naast $O_2$ heeft de $G_2(4)$ schier achthoek $O_1$ nog andere interessante deelmeetkunden.

**Theorem A.1.3.** Onderstel dat $H$ een maximale deelgroep is van $G_2(4):2$ isomorf met $J_2:2$. Stel dat $X$ gelijk is aan de verzameling van de centrale involuties van $G_2(4):2$ die bevat zijn in $H$. Dan is $X$ een deelruimte van $O_1$, en de deelmeetkunde geïnduceerd op $X$ door de rechten van $O_1$ die al hun punten in $X$ hebben, is isomorf met met Hall–Janko schier achthoek $HJ$. Omgekeerd, wordt elke deelmeetkunde van $O_1$ isomorf met $HJ$ op deze manier bekomen.
Met de ontdekking van de $G_2(4)$ schier achthoek $O_1$, kunnen we nu volgende keten van schier veelhoeken neerschrijven:

$$H(2, 1) \subset H(2)^D \subset HJ \subset O_2.$$ 

Deze keten heeft sterke gelijkenissen met de Suzuki keten $L_3(2) \leq U_3(3) \leq J_2 \leq G_2(4) \leq S uz$ van enkelvoudige groepen. De volgende karakterisaties van de “Suzuki keten schier veelhoeken” werden bekomen in Hoofdstuk 6 van de thesis. De bewijzen steunen op de theorie van de valuaties van schier veelhoeken die ontwikkeld werd in \[59,64\].

**Theorem A.1.4.** (a) Op isomorfie na is de duale split Cayley veralgemeende zeshoek $H^D(2)$ de unieke schier zeshoek van orde $(2, 2)$ die $H(2, 1)$ bevat als een volle isometrisch ingebedde meetkunde.

(b) Op isomorfie na is de Hall-Janko schier achthoek $HJ$ de unieke schier achthoek van orde $(2, 4)$ die $H(2)^D$ bevat als een volle isometrisch ingebedde meetkunde.

(c) Op isomorfie na is de $G_2(4)$ schier achthoek $O_1$ de unieke schier achthoek van orde $(2, 10)$ die $HJ$ bevat als een volle isometrisch ingebedde meetkunde.

Eén van de belangrijkste open problemen in de theorie van de veralgemeende veelhoeken is het al of niet bestaan van half-oneindige veralgemeende veelhoeken. Dit zijn veralgemeende veelhoeken van orde $(s, t)$ waarbij $s \geq 2$ eindig en $t$ oneindig is. Het volgende werd aangetoond in Hoofdstuk 4.

**Theorem A.1.5.** Als $q \in \{2, 3, 4\}$, dan zijn er geen half-oneindige veralgemeende zeshoeken van orde $(q, t)$ die $H(q)$ of $H(q)^D$ als volle deelmeetkunde bevatten.

Het bewijs in het geval van een deelmeetkunde isomorf met $H(4)^D$ steunde op volgend resultaat uit Hoofdstuk 3, dat werd bekomen met behulp van computerberekeningen.

**Theorem A.1.6.** De duale split Cayley hexagon $H(4)^D$ heeft geen afstands-2-ovoiden, d.w.z. geen puntenverzamelingen die elke rechte snijden in een singleton.

Hoofdstuk 3 is in het algemeen gewijd aan het computationeel aspect van de thesis, met beschrijving van algoritmen en computationele technieken. De volgende resultaten over veralgemeende zeshoeken werden eveneens in Hoofdstuk 4 aangetoond.

**Theorem A.1.7.** Als $q \in \{2, 4\}$, dan zijn er geen veralgemeende zeshoeken die $H(q)$ als een eigenlijke volle deelmeetkunde bevatten.

**Theorem A.1.8.** Elke schier zeshoek met drie punten per rechte die een isometrisch ingebedde volle deelmeetkunde heeft isomorf met $H(2)^D$, is isomorf met ofwel $H(2)^D$ ofwel $T(2, 8)$. 
A.2. Deel 2 (Hoofdstukken 7 t.e.m. 9)

Als $R$ een ring is, dan wordt elke verzameling van de vorm $A = A_1 × · · · × A_n$, waarbij $A_i$ een niet-ledige eindige deelverzameling van $R$ is, een eindig rooster van $R^n$ genoemd. We zeggen dat zo’n rooster aan Conditie (D) voldoet als voor elke $i ∈ \{1, 2, ..., n\}$ en alle $α, β ∈ A_i$ met $α ≠ β$, het element $α − β$ geen nuldele is van $R$. Er kan aangetoond worden dat als $A$ aan Conditie (D) voldoet, dan bestaat er voor elke veelterm $f ∈ R[t_1, ..., t_n]$ een unieke veelterm $r_A(f) ∈ R[t_1, ..., t_n]$ zodat $\deg t_i r_A(f) ≤ |A_i| − 1$ voor alle $i ∈ \{1, 2, ..., n\}$ en $f(x) = r_A(f)(x)$ voor alle $x ∈ A$. Hiervan gebruik makend, werden in Hoofdstuk 8 van de thesis bewijzen gegeven van de "Combinatorial Nullstellensatz" en de "Punctured Combinatorial Nullstellensatz". In Hoofdstuk 8 van de thesis werd eveneens volgende nieuwe veralgemenening van het klassieke Chevalley-Waring theorema bewezen.

**Theorem A.2.1.** Onderstel dat $A_1, ..., A_n, B_1, ..., B_n$ niet-ledige deelverzamelingen zijn van $\mathbb{F}_q$ zodat $B_i ⊆ A_i$ voor alle $i ∈ \{1, 2, ..., n\}$. Stel $A = A_1 × · · · × A_n$ en $B = B_1 × · · · × B_n$. Onderstel eveneens dat $f_1, ..., f_r ∈ \mathbb{F}_q[t_1, ..., t_n]$ zodat $(q−1)\sum_{j=1}^r \deg f_j < \sum(|A_i| − |B_i|)$ en definieer $Z_A = \{x ∈ \prod A_i | \forall j f_j(x) = 0\}$. Dan geldt dat $Z_A \cap (A \setminus B) ≠ \emptyset$ als $Z_A \cap B ≠ \emptyset$.

In Hoofdstuk 9 van de thesis, werd volgende veralgemenening van het Alon-Füredi theorema bewezen, en vervolgens toegepast in verschillende gebieden zoals de codeertheorie, theoretische computerwetenschappen en eindige meetkunde.

**Theorem A.2.2 (Veralgemeend Alon-Füredi Theorema).** Onderstel dat $A = A_1 × · · · × A_n \subseteq \mathbb{R}^n$ een eindig rooster is die aan Conditie (D) voldoet. Voor elke $i ∈ \{1, ..., n\}$, stel $a_i = |A_i|$ en noem $b_i$ een natuurlijk getal die voldoet aan $1 ≤ b_i ≤ a_i$. Onderstel eveneens dat $f ∈ R[t_1, ..., t_n]$ een niet-nul polynoom is die voldoet aan $\deg t_i f ≤ a_i − b_i$ voor alle $i ∈ \{1, ..., n\}$. Definieer $U_A = \{x ∈ A | f(x) ≠ 0\}$. Als $N ∈ \mathbb{N}$ zodat $\sum b_i ≤ N ≤ \sum a_i$, dan stelt $m(a_1, ..., a_n; b_1, ..., b_n; N)$ de minimale waarde voor bereikt door alle producten $y_1y_2...y_n$, waarbij $\sum y_i = N$ en elke $y_i$ behoort tot het interval $[b_i, a_i]$. Dan geldt

$$|U_A| ≥ m(a_1, ..., a_n; b_1, ..., b_n; \sum_{i=1}^n a_i − \deg f).$$

Bovendien kan voor zulke $R$, $A_1, ..., A_n$, $b_1, ..., b_n$ een polynoom $f$ gevonden worden waarvoor de ondergrens bereikt wordt.

De volgende gevolgen van het veralgemeend Alon-Füredi theorema betreffen nieuwe resultaten in de eindige meetkunde. Een partiële cover of PG$(n, q)$ wordt gedefinieerd als een collectie $\mathcal{H}$ van hypervlakken die niet alle punten bedekken. De punten die niet bedekt worden, worden gaten genoemd.

**Theorem A.2.3.** Onderstel dat $\mathcal{H}$ een partiële cover van PG$(n, q)$ is die $k ≥ 1$ hypervlakken bevat. Dan heeft $\mathcal{H}$ tenminste $m(q, ..., q; nq − k + 1)$ gaten.

**Theorem A.2.4.** Als $S$ een verzameling van $k$ punten in AG$(n, q)$ is, dan bestaan er tenminste $m(q, ..., q; nq − k + 1) − 1$ hypervlakken van AG$(n, q)$ die disjunct zijn met $S$.

De volgende versie van het Schwartz-Zippel lemma (die rekening houdt met multipliciteiten) werd eveneens aangetoond.
Theorem A.2.5. Onderstel dat $A = \prod_{i=1}^{n} A_i \subseteq \mathbb{R}^n$ een eindig rooster is met $|A_1| \geq \cdots \geq |A_n|$ die aan Conditie (D) voldoet. Voor elk niet-nul polynoom $f \in \mathbb{R}[t_1, \ldots, t_n]$ geldt dan dat

$$\sum_{x \in A} m(f, x) \leq (\deg f) \prod_{i=1}^{n-1} |A_i|,$$

waarbij $m(f, x)$ de multipliciteit van $f$ in $x$ voorstelt.
