Sensory-Neuropathy-Causing Mutations in ATL3 Cause Aberrant ER Membrane Tethering

Graphical Abstract

Highlights

- HSAN-causing ATL3 mutants are less fusogenic but retain their dimerization capacity

- Recombinant mutant ATL3 proteins cause excessive liposome tethering

- In cells, HSAN-causing ATL3 mutants lead to collapse of the ER

- Volume EM revealed that ER collapse is hallmarked by laterally tethered ER tubules

In Brief

Mutations in atlastins (ATLs), the ER fusion proteins in mammals, cause neurodegeneration. Using volume EM in patient fibroblasts, Krols et al. reveal that HSAN-causing mutations in ATL3 promote aberrant ER tethering due to a defect in an intermediate step in the functional cycle of the ATL3 GTPase.
Sensory-Neuropathy-Causing Mutations in ATL3 Cause Aberrant ER Membrane Tethering

SUMMARY

The endoplasmic reticulum (ER) is a complex network of sheets and tubules that is continuously remodeled. The relevance of this membrane dynamics is underscored by the fact that mutations in atlastins (ATLs), the ER fusion proteins in mammals, cause neurodegeneration. How defects in this process disrupt neuronal homeostasis is unclear. Using electron microscopy (EM) volume reconstruction of transfected cells, neurons, and patient fibroblasts, we show that hereditary sensory and autonomic neuropathy (HSAN)-causing ATL3 mutants promote aberrant ER tethering hallmarked by bundles of laterally attached ER tubules. In vitro, these mutants cause excessive liposome tethering, recapitulating the results in cells. Moreover, ATL3 variants retain their dimerization-dependent GTPase activity but are unable to promote membrane fusion, suggesting a defect in an intermediate step of the ATL3 functional cycle. Our data show that the effects of ATL3 mutations on ER network organization go beyond a loss of fusion and shed light on neuropathies caused by atlastin defects.

INTRODUCTION

The endoplasmic reticulum (ER) is an intricate network of sheets and tubules that spreads throughout the cytoplasm and is continuous with the nuclear envelope. The distinct morphologies of the ER subdomains are determined by a tug of war between proteins promoting the high membrane curvature found in ER tubules and sheet edges on the one hand and proteins segregating to and stabilizing ER sheets on the other. Adding to the complexity of this organelle, the network is continuously being remodeled through the extension and retraction of tubules, tubule fusions, and ring closures (Westrate et al., 2015).

In metazoans, homotypic fusion of ER tubules is mediated by a class of membrane-bound dynamin-like GTPases known as atlastins (ATLs) (Hu et al., 2009; Orso et al., 2009). The ATL proteins are composed of a large N-terminal cytoplasmic domain, two closely spaced transmembrane helices that anchor the protein in the ER membrane, and a C-terminal amphipathic helix. The N-terminal domain consists of a GTPase domain (G domain) connected via a flexible linker to a three-helix bundle (3HB) middle domain (Bian et al., 2011; Byrnes and Sondermann, 2011; Liu et al., 2012). Homotypic ER membrane fusion is mediated by the GTP-dependent homodimerization of ATLs in opposing membranes, promoting tight membrane tethering and eventually membrane fusion (Byrnes and Sondermann, 2011; Byrnes et al., 2013; Hu and Rapoport, 2016; Liu et al., 2015; O’Donnell et al., 2017; Saini et al., 2014) (see Figure S1). Although the actual fusion mechanism has not been entirely elucidated, it is clear that the ATL transmembrane domains and the C-terminal tail are crucial for membrane fusion, presumably by destabilizing the membranes to promote lipid mixing (Liu et al., 2012; Moss et al., 2011).

Mammals have three ATLs, which share high sequence homology but are differentially expressed. ATL1 is predominantly expressed in the brain, whereas ATL2 and ATL3 show a more ubiquitous expression pattern (Rismanchi et al., 2008). In addition, the three ATL proteins appear to have different fusogenic capacities, with ATL1 being the stronger fusogen and ATL3 a much weaker one (Hu et al., 2015; O’Donnell et al., 2017). In line with this, selective loss of ATL3 has very little effect on ER...
morphogenesis, whereas ATL1 alone is sufficient to rescue the loss of both ATL2 and ATL3 in COS-7 cells (Hu et al., 2015).

Mutations in ATL1 have been identified in patients suffering from degeneration of upper motor neurons (hereditary spastic paraplegia [HSP]) as well as peripheral sensory neurons (hereditary sensory and autonomic neuropathy [HSAN]) (Guely et al., 2011; Zhao et al., 2001). More recently, two autosomal-dominant missense mutations in ATL3 (p.Tyr192Cys and p.Pro338Arg, hereafter referred to as ATL3Y192C and ATL3P338R) were found to cause sensory neurodegeneration (Fischer et al., 2014; Kornak et al., 2014). HSP patients show progressive spasticity in the lower limbs, whereas individuals affected by HSAN have a characteristic loss of pain perception and variable degrees of autonomic dysfunction. Common to both diseases is a degeneration of neurons with particularly long axons. Interestingly, mutations in additional ER shaping proteins such as REEP1, REEP2, Spastin, and Reticulon 2 cause similar phenotypes (Hubner and Kurth, 2014), clearly showing that maintaining the dynamic structure of the ER throughout these very long axons is pivotal for neuronal survival. What is less clear, however, is how defects in ER shaping underlie axonal degeneration. We therefore investigated whether disease-causing mutations in ATL3 alter its functionality and how this affects ER shaping and dynamics. Here, we reveal for the very first time evidence for aberrant ER membrane tethering caused by ATL3 mutations. Using volume electron microscopy, we provide unprecedented insights in the structure of the ER tangles resulting from this aberrant tethering in cells expressing mutant ATL3. Given the redundancy of the three ATL proteins, this aberrant ER membrane tethering likely represents a major contribution to the axonal degeneration observed in patients.

RESULTS

Mutations in ATL3 Disrupt ER Morphogenesis

We recently uncovered two novel mutations in ATL3 to be causative for HSAN and with this finding added ATL3 to a growing list of ER-shaping proteins involved in neurodegeneration (Fischer et al., 2014; Kornak et al., 2014). To study the impact of the ATL3 Y192C and P338R mutations on ER morphology, we imaged COS-7 cells expressing GFP-tagged wild-type (WT) and mutant versions of ATL3 (Figure S2). ATL3WT was targeted to the ER, where it was present mostly in the highly curved membranes of ER tubules (Figure 1A). ATL3Y192C or ATL3P338R similarly localized to the tubular ER (Figure 1A). However, while ATL3WT spread evenly throughout the ER network, mutant ATL3 appeared in patches along the tubules in the peripheral ER and was present mostly in an ER region near the nucleus (Figure 1A). Similar phenotypes were observed in HeLa cells (data not shown). The peripheral ER network morphology was dramatically altered in cells expressing mutant ATL3. While the ER in control cells formed a highly interconnected tubular network in the periphery of the cell (Figure 1B), cells transfected with ATL3Y192C or ATL3P338R displayed a peripheral ER network that was far more disperse (Figure 1B), as quantified by the significant decrease in density of three-way junctions per cell area (Figures 1B and 1C). Concordantly, expression of either mutant ATL3 resulted in larger zones within the cell periphery that were devoid of ER tubules, defined as ER sparsity (Figures 1B and 1D).

Besides ER morphogenesis, several reports have suggested a role for ATLs in the Golgi apparatus (Namekawa et al., 2007; Rismarchi et al., 2008). Neither WT nor mutant ATL3 was found to localize to the Golgi complex of HeLa or COS-7 cells, and over-expression of mutant ATL3 was not found to alter Golgi apparatus morphology in these cells (Figure S3), indicating that a disruption of the ER tubular network is the main hallmark of these mutations in ATL3.

ER Continuity Is Maintained in Cells Overexpressing Mutant ATL3

A key feature of the ER is that despite the continuous membrane rearrangements, it maintains a single continuous lumen. In a recently reported in vitro reconstitution model of the ER, blocking ATL-mediated fusion resulted in fast fragmentation of the network (Powers et al., 2017). Given the severe effect of the mutations in ATL3 on ER morphology, we examined whether ER continuity was maintained in cells expressing mutant ATL3 using a photoactivatable GFP targeted to the ER lumen (PA-GFP-KDEL) (Jones et al., 2009). Photo-induced activation of this fluorescent protein allows tracking PA-GFP targeted to the ER lumen (PA-GFP-KDEL) as it pervades from the site of activation throughout the ER network and thus allows assessing its luminal continuity (Video S1). In addition, the rate at which the fluorophores spread throughout the ER can be used as a measure of network connectivity (Figure S4). In cells expressing ATL3WT, activated PA-GFP rapidly diffuses from its site of activation throughout the ER network (Figure 2A). Photoactivation in similar regions of the ER in mutant-ATL3-expressing cells comparably resulted in the spread of the activated fluorophores throughout the entire network, indicating that luminal continuity is not disrupted in these cells (Figure 2A). However, in agreement with a loss of three-way junctions, analysis of the rate at which the fluorescence intensity increased at discrete distances from the site of activation shows a significantly slower emergence of activated PA-GFP in distal regions of cells expressing ATL3Y192C or ATL3P338R compared to cells expressing ATL3WT (Figures 2B
While other characteristics of network topology may also contribute to an altered diffusion speed, this slowed diffusion through the ER network is in agreement with a failure to establish an intricately connected ER network in cells overexpressing mutant ATL3 (Figure 1). Combined, these findings show that mutations in ATL3 affect the formation of three-way junctions without causing network fragmentation.

Overexpression of Mutant ATL3 Causes a Deficit in ER Membrane Fusion

Three-way junctions represent the nodes that interconnect the tubular ER and are established through homotypic ER membrane fusion. The loss of junctions in ATL3 mutant cells suggests that mutations in ATL3 disrupt ER membrane fusion. Therefore, we performed live-cell imaging of COS-7 cells to monitor tubule fusion events (Figure 3A; Videos S2 and S3). Compared to control cells, overexpression of ATL3WT significantly increased the ER membrane fusion success rate from 67% ± 2% to 78% ± 2% (Figure 3B). Expression of mutant ATL3, on the other hand, resulted in a dramatic reduction of this success rate to 23% ± 2% in the case of ATL3Y192C and 40% ± 2% in the case of ATL3P338R (Figure 3B). Hence, the efficiency of ER membrane fusion is impaired dramatically when ATL3 carrying the HSAN-causing mutations is expressed, indicating that the mutations

Figure 2. ER Continuity Is Not Lost in ATL3 Mutant Cells

ER-targeted photoactivatable GFP (PA-GFP-KDEL) was imaged in COS-7 cells transfected with ATL3WT, ATL3Y192C, or ATL3P338R (see Video S1). (A) PA-GFP-KDEL was activated in a small area next to the nucleus. The frame just prior to activation is indicated as t = 0 s and the frame immediately following activation as t = 1 s. To clearly show the peripheral ER network, the last frame is also shown as a high-contrast, inverted grayscale image. Scale bar, 10 μm. (B) Ribbon plots show the mean fluorescence intensity ± SEM for cells expressing ATL3WT (red), ATL3Y192C (blue), and ATL3P338R (green) at fixed distances (8, 12, 16, and 20 μm) from the site of activation (see also Figure S4). (C) Mean half-time to reach maximum intensity ± SEM is plotted and statistical analysis was performed using two-way ANOVA followed by Tukey’s multiple comparisons test. *p < 0.05; **p < 0.01; ****p < 0.0001; n = 40–75 regions of interest per distance in 10–17 cells per genotype.
cause a defect in the mechanism whereby ATL3 induces membrane fusion.

**Mutations in ATL3 Interfere with GTP Hydrolysis-Dependent Dimerization**

To probe the possible mechanistic consequences of the Y192C and P338R mutations in the functional cycle of ATL3, we compared the biochemical and biophysical properties of the soluble domain of ATL3WT, ATL3Y192C, and ATL3P338R encompassing the GTPase domain, the linker and the 3HB middle domain (Figure S5A). Prior structural studies on ATL1 had revealed the existence of at least two distinct conformations of ATL1, termed “extended” and “crossover” (Figure S1), which were hypothesized to correspond to the prefusion and postfusion states of ATL1, respectively (Bian et al., 2011; Byrnes and Sondermann, 2011). In the extended conformation, for which a crystal structure of ATL3 was also recently solved (O’Donnell et al., 2017), the α-helical 3HB middle domain packs tightly against the G domain, enforced mainly by hydrophobic interactions (Figure 4A and S1). Interestingly, the Y192 and P338 residues in ATL3 localize to this hydrophobic core (Figure 4A). At the same time, these amino acid residues pack against the hinge region that relays the drastic structural transitioning of ATL3 into its crossover conformation upon hydrolysis of GTP (Figure 4A). It is thus clear that both mutations affect residues that are positioned within a functional switch region in ATL3 (Figure 4A). The functional relevance of these residues is further underscored by the fact that mutations at the equivalent positions in the homologous ATL1 cause HSP (de Bot et al., 2013; McCorquodale et al., 2011).

To enable comparative biochemical and biophysical characterization of ATL3WT, ATL3Y192C and ATL3P338R, we produced and purified recombinant WT and mutant proteins comprising residues 22-442 (Figures S5A and S5B). We verified the equivalence of the folding state of the three recombinant proteins by circular dichroism (CD), which revealed mean residual ellipticity (MRE) profiles consistent with the presence of a mix of α-helical and β-strand secondary structural elements in ATLs (Figure S5C). We first tested whether the HSAN-causing mutations interfere with the GTPase activity of ATL3. We found that the GTPase activity of ATL3WT displayed significant cooperativity, as indicated by the sigmoidal relationship between the enzymatic activity and substrate concentration (Figure 4B). Such cooperativity is in agreement with dimerization dependence of the ATL3 GTPase activity. Similar analysis of the catalytic activity of ATL3Y192C and ATL3P338R revealed that these mutant proteins not only retain the competence to hydrolyze GTP but also maintain the ability to dimerize following GTP binding (Figure 4B).

Following GTP hydrolysis, the ATL3 dimer is expected to undergo a conformational change whereby both molecules switch from their initial conformation, most likely resembling the extended structure, to a stable crossover dimer (Figures 4A and S1) (Bian et al., 2011; Byrnes and Sondermann, 2011; Byrnes et al., 2013; Hu and Rapoport, 2016; Liu et al., 2015; O’Donnell et al., 2017; Saini et al., 2014). In vitro, these stable dimers form in the presence of the non-hydrolyzable GTP analog GTPγS and the transition state analog GDP.AlF4− (Morin-Leisk et al., 2011; Saini et al., 2014; Winsor et al., 2017). To examine oligomerization of the ATL3 22-442 proteins in solution, we performed size-exclusion chromatography (SEC) coupled to multi-angle laser light scattering (MALLS). While the SEC retention times correlate with the hydrodynamic volume of the particles, static light scattering allows molecular weight (MW) determination regardless of shape (Table S1) and therefore the possible oligomerization state of a given protein. We found that in the absence of nucleotide, all three proteins displayed the same SEC-MALLS profile, consistent with monomeric states averaging 48.1 kDa compared to the theoretical MW of 47.9 kDa (Figure 4C; Table S1). In the presence of GDP, these profiles

(legend on next page)
The increase in apparent hydrodynamic radius of the proteoliposomes upon tethering was measured using dynamic light scattering. Tethering was induced by adding 5 mM GTP at the indicated time point. See also Figure S5. Mean ± SEM of a representative experiment is plotted.

**Mutations in ATL3 Result in Excessive ER Tubule Tethering**

While being essential for membrane fusion, several studies have shown that stable crossover dimer formation is dispensable for membrane tethering (Saini et al., 2014; Winsor et al., 2017). Therefore, to test for the membrane tethering capacity of ATL3WT, we replaced the transmembrane region of ATL3 with 10 histidines (termed ATL3 ΔTM). Since the absence of transmembrane helices of ATL3 prevents membrane fusion (Liu et al., 2012; Saini et al., 2014), dynamic light scattering (DLS) can be used to analyze the tethering capacity of WT or mutant ATL3 in vitro by measuring the apparent increase in size of the proteoliposomes upon addition of GTP (Figure 4E) (Liu et al., 2015). Indeed, ATL3WT proteoliposomes showed an increase in the mean radius upon the addition of GTP, reaching a plateau at ~255 nm indicating steady-state tethering between a subset of liposomes at each given time point (Figure 4E).

Unexpectedly, both disease-causing mutations in ATL3 did not only retain liposome-tethering activity; in fact, they appeared hyperactive, resulting in a much more pronounced accumulation of tethered liposomes after the addition of GTP (Figure 4E). These data suggest that while the mutant proteins fail to attain a stable crossover dimer in solution (Figure 4C), their membrane-tethering capacity is unaffected, showing that they do establish dimers in trans when associated with liposomes. Moreover, the defect caused by these mutations results in hyperactive tethering compared to ATL3WT, causing an accumulation of tethered liposomes in vitro (Figure 4E).

To address whether this observation was relevant in cells expressing mutant ATL3, we applied focused-ion-beam scanning electron microscopy (FIBSEM), which allowed us to resolve the ultrastructure of the ER in large volumes at nanometer-scale resolution (Kremer et al., 2015). Volume electron microscopy (EM) images of cells overexpressing ATL3WT revealed that the ER in these cells exhibits a typical morphology hallmarkned by an elaborate network of sheets (Figure 5, top; Video S4). Analysis of a similar region in the periphery of a HeLa cell expressing ATL3Δ192C confirmed our earlier findings that the ER is sparsely connected in these cells and consists of long unbranched tubules (Figure 5, middle; Video S5). In addition, we observed several tubules that were attached laterally without the presence of a junction, as indicated by the differently colored ER tubules in our 3D reconstruction (Figure 5, middle; Video S5). This became even clearer when analyzing the perinuclear region in the same cell expressing ATL3Δ192C. The collapsed ER (as shown in Figure 4) consisted of a severely anomalous tangle of mostly ER tubules interspersed with a few ER sheets (Video S6). Reconstruction of a part of the ER tangle in this perinuclear region clearly showed the presence of long unbranched tubules that appear tethered laterally without being interconnected, again underscoring that mutant ATL3 is still capable of mediating membrane tethering, but not ER tubule fusion (Figure 5, bottom; Video S7). In conclusion, in agreement with the in vitro data, the loss of fusogenic capacity in these proteins is accompanied by excessive membrane tethering that has a major impact on ER morphogenesis in cells expressing mutant ATL3.

**Aberrant ER Membrane Tethering in HSAN Patient Fibroblasts and Neurons**

So far, all our in cellulo data were generated from cells overexpressing WT or mutant ATL3. To exclude any possible artifact due to overexpression, we derived skin fibroblasts from a patient carrying the ATL3Y192C mutation (Figure 6). Staining for endogenous KDEL in these cells revealed discernable ER clustering, particularly in the perinuclear region (Figure 6A). This became
even more apparent using transmission EM. While control fibroblasts displayed a highly connected and well-spread ER, we frequently observed clusters of parallel-oriented unbranched ER membranes in the patient fibroblasts (Figures 6B and S6).

As expected from the transmission EM (TEM) images, FIBSEM analysis of these patient cells indeed revealed several regions of anomalous tethering of ER membranes (Figure 6C). These observations in HSAN-patient-derived cells therefore confirm that aberrant ER tubule tethering caused by mutations in ATL3 is relevant also in conditions of endogenous ATL3 expression.

To assess whether this tethering is relevant for neurodegeneration, we expressed WT or mutant ATL3 in primary mouse cortical neurons using lentiviral transduction (Figure 7). In these cells, the ER marked by ATL3-GFP was found to spread from a dense structure in the soma throughout the neurites regardless of whether WT or mutant ATL3 was expressed, indicating that the mutations do not prevent the generation of neurites or the spread of the ER therein (Figure 7A). However, in the neurons expressing ATL3Y192C or ATL3P338R, we observed a higher ER density within the soma compared to cells expressing ATL3WT, similar to what we observed in COS-7 or HeLa cells (Figures 1 and 5). While such dense ER clusters (Figure 7A, arrowheads) were only observed in less than 10% of neurons overexpressing ATL3WT, ~70% of cells expressing mutant ATL3 exhibited this phenotype, showing that this is a major hallmark of HSAN-causing mutations in ATL3 (Figure 7B). To show that these structures indeed represent an altered distribution of ATL3-GFP throughout the cells, we measured relative GFP intensities along single neurites starting from the center of the soma, which confirmed that neurons expressing mutant ATL3-GFP retained a larger fraction of the total GFP signal within this perinuclear ER structure compared to ATL3WT-expressing cells (Figure 7C). In order to resolve the ultrastructure of the ER in these clusters, we performed FIBSEM imaging on these neurons using correlative light EM (CLEM) to identify the neurons expressing GFP-tagged ATL3 (Figure 7D). Similar to what we observed in patient fibroblasts, FIBSEM analysis of these patient cells indeed revealed several regions of anomalous tethering of ER membranes (Figure 6C).

Figure 5. Mutations in ATL3 Result in Aberrant Tethering of Unbranched Tubules
Volume electron microscopy of HeLa cells expressing WT (top) or mutant (middle and bottom) ATL3 was performed using focused-ion-beam scanning electron microscopy (FIBSEM). A representative section of each cell is shown on the left, and a higher magnification of the marked area is shown in the middle. A 3D model obtained by manual segmentation of a fraction of the ER (as marked in color on the FIBSEM slice) is shown on the right. Differently colored tubules indicate that these are discontinuous within the reconstructed volume. See also Videos S4, S5, S6, and S7. Scale bars, 500 nm; N, nucleus.
fibroblasts, the neurons expressing ATL3Y192C also showed distinct regions of tethered ER within the high-density ER structures that were observed by light microscopy (Figure 7E; Videos S8 and S9). Such clusters were never observed in primary cortical neurons overexpressing ATL3WT (Figure S7). In summary, these data show that in both patient fibroblasts and neuronal cell, mutations of ATL3 lead to a partial collapse of the ER due to excessive membrane tethering, further underscoring the physiological relevance of our findings.

DISCUSSION

In this study, we have provided insights into how disease-related mutations in ATL3 interfere with the protein’s functional cycle
(legend on next page)
required for membrane fusion. Importantly, we show that such functional defects impact the structure and integrity of the ER both in cells overexpressing pathogenic variants of ATL3 and in patient-derived fibroblasts. Indeed, the formation of new junctions through ER tubule fusion mediated by the ATL GTPases is essential for the continuous remodeling of the ER, defects in which cause axonal degeneration in diseases such as HSAN and HSP (Fischer et al., 2014; Guelty et al., 2011; Kornak et al., 2014; Zhao et al., 2001). Here, we show that in addition to a loss of fusion activity, the HSAN-causing ATL3 variants cause lateral tethering and tangling of ER membranes.

Recent structural and biochemical studies on human ATL1-3 and Drosophila ATL (dATL) have proposed a model for ATL-mediated membrane fusion in which the G domains of ATL1 dimerize in trans upon GTP binding (Figure S1A) and that GTP hydrolysis promotes the formation of a tight crossover dimer (Figure S1B), bringing both membranes in close apposition and thereby driving membrane fusion (Bian et al., 2011; Byrnes and Sondemann, 2011; Byrnes et al., 2013; Liu et al., 2015; O’Donnell et al., 2017; Saini et al., 2014; Winsor et al., 2017). Our data now show that the disease-causing ATL3 variants do not interfere with the initial steps of the functional cycle leading up to G domain dimerization, nor do they affect the allosteric properties (Figure 4). However, the mutant proteins do show a different behavior in the steps following initial dimerization. The ATL3Y192C and ATL3P338R mutant proteins suffer from a reduced dimerization propensity in the presence of GTPyS or GDP+AlF4− (Figure 4), suggesting that the mutants fail to establish the stable crossover dimer conformation following GTP hydrolysis. As this stable dimer is an absolute prerequisite to cross the energy barrier required for merging lipid bilayers (Winsor et al., 2017), failure to attain this conformation offers an attractive explanation for the inability of the mutant ATL3 to support membrane fusion, as reflected by the ER network connectivity deficit observed in COS-7 cells (Figures 1, 2, and 3).

In contrast to fusion, the preceding membrane-tethering step does not depend on the stable crossover dimer (Liu et al., 2015; Morin-Leisk et al., 2011; Saini et al., 2014; Winsor et al., 2017). Interestingly, one of the most striking ER defects we observed in cells expressing HSAN-causing mutations in ATL3 was the presence of extensive ER membrane tethering, as revealed by volume EM. This unique phenotype was characterized by the presence of bundles of ER tubules running in parallel over a large number of FIBSEM slices (Figure 5; Videos S6 and S7). This aberrant tethering occurred mainly in a collapsed, high-density region of the ER near the nucleus in cell lines. Although we currently do not have direct structural data to rationalize the underlying mechanism, we hypothesize that HSAN-causing mutations in ATL3, located in the interface between the G and the 3HB domain, prevent the protein from proceeding through its functional cycle following trans-dimerization and GTP hydrolysis. Rather than completing their cycle followed by dissociation of the dimer, the proteins seem stalled or blocked in the membrane tethering stage, causing excessive membrane tethering in cell lines, fibroblasts, and neurons (Figures 5, 6, and 7). These interactions were not retrieved in the SEC-MALLS experiments, indicating that they are transient in solution and might require further stabilization by membrane association and the 2-dimensional spatial confinement of the membrane (Winsor et al., 2017). Indeed, the in vitro tethering assay confirmed that both disease-causing mutations in ATL3 promote excessive liposome tethering compared to the WT protein (Figure 4).

Together, our findings are in agreement with a model in which GTP binding and hydrolysis drives ER membrane tethering through ATL trans-dimerization. Subsequent membrane fusion relies on the formation of a stable crossover dimer bringing the membranes in close apposition, resulting in a new three-way junction. While the HSAN-causing mutations in ATL3 do not abrogate GTP binding or hydrolysis, the mutant proteins fail to completely execute the subsequent conformational changes required to form a stable crossover dimer, rendering the mutant ATL3-fusion deficient. Underscoring the relevance of this stable crossover conformation to reset the protein for a new round of tethering and fusion (O’Donnell et al., 2017), the inability of both mutants to proceed to this step of the ATL functional cycle causes aberrant membrane tethering that leads to a partial collapse of the ER network, strongly affecting ER dynamics.

ATL1 is the predominant isoform in the nervous system (Kornak et al., 2014; Rismanchi et al., 2008) and is also the ATL with the highest intrinsic fusogenic capacity (Hu et al., 2015; O’Donnell et al., 2017). Therefore, a defect in ER fusion is thought to underlie the HSP phenotype in most of the patients carrying mutations in ATL1 (Ujiqgin et al., 2015). ATL3, on the other hand, was found to be a much weaker fusogen (O’Donnell et al., 2017), and loss of ATL3 has only marginal effects on overall ER morphology (Hu et al., 2015). Therefore, in the case of the dominant missense mutations in ATL3 causing HSAN, loss of ER fusion is far less likely to be the main factor contributing to disease. In contrast, a partial collapse of the ER network caused by excessive membrane tethering in the ATL3Y192C and ATL3P338R mutants might have a much higher impact on neuronal functioning. In agreement with this, ER tangling was also detected in patient fibroblast where the mutant ATL3 is expressed at physiologically relevant levels (Figure 6). Similarly, ER tangling was identified in the electron microscope (right, scale bar, 2 μm).

Figure 7. ER Tangling Is Observed in Primary Cortical Neurons Expressing Mutant ATL3
(A) Mouse primary cortical neurons were transduced with ATL3-GFP. Higher magnifications of ATL3-GFP in the boxed areas are shown in a fluorescence intensity color code as indicated in (C). Arrowheads mark dense ER clusters in the mutant neurons. Scale bar, 20 μm.
(B) The fraction of cells expressing WT or mutant ATL3 displaying ER tangling (as marked by arrowheads in A) was determined in 3 independent cortical neuron isolations (n = 39–53 cells). Mean ± SEM is plotted. **p < 0.001 in a one-way ANOVA test.
(C) A “straightened” version of a 30 μm neurite tracing from the cells shown in (A) is shown for each genotype, and normalized GFP and nuclear stain fluorescence intensity are plotted in function of the position along this trace. Mean ± SEM is plotted (n = 30–35 cells).
(D) Primary cortical neurons expressing GFP-tagged ATL3Y192C (left). Scale bars, 100 μm in the overview image and 20 μm in the zoomed region. The same neuron was identified in the electron microscope (right, scale bar, 2 μm).
(E) A cluster of tangled ER membranes was identified in the perinuclear area marked in (D), XZ and YZ projections of the positions marked by arrowheads and a 3D reconstruction of the tangled ER membranes are shown. Scale bar, 500 nm. Volume EM for a cortical neuron expressing ATL3WT is shown in Figure S7.
tangling was observed in neurons expressing mutant ATL3, affecting the distribution of the ER within these cells (Figure 7). We hypothesize that ER tethering disturbs normal ER membrane dynamics, and most likely interferes with the organization of different ER subdomains playing various roles in neuronal homeostasis (English and Voeltz, 2013). In agreement with our hypothesis, no measurable defect in ER fusion was found for several HSP-causing variants in ATL1, including the most commonly identified R239C mutation (Ulengin et al., 2015), indicating that defects other than loss of fusion contribute to neurodegeneration in these patients. Since little is currently known about the function of the ER within axons, studying the effect of disease-causing mutations in ATLs and other ER-shaping proteins (Hubner and Kurth, 2014) may shed more light on the role of axonal ER in neuronal homeostasis and disease.

EXPERIMENTAL PROCEDURES

Plasmids, Cell Lines, and Transfections
All ATL3-expressing vectors were created using Gateway recombination system (Thermo Fisher Scientific). The pCI-mRubyKDEL vector was a gift from Dr. Jörg Wiedenmann (Kredel et al., 2009). The PA-GFP-KDEL vector was a gift from Dr. Vicky Claire Jones (Jones et al., 2009).

Transient transfections of HeLa and COS-7 cells were performed using Lipofectamine-LTX (Thermo Fisher Scientific). Mouse cortical neurons were extracted from embryonic day 15.5 (E15.5) C57BL/6 embryos, and lentiviral transduction was used to express ATL3-GFP. Primary dermal fibroblasts were generated from a 66-year-old female patient with a c.575A>G (p.Tyr192Cys) mutation in the ATL3 gene. The procedures were approved by the Ethics Committee of the Christian-Albrechts University Medical School under the reference number A 145/11.

Immunofluorescence Microscopy
HeLa cells, COS-7 cells, mouse cortical neurons, and human skin fibroblasts were cultured, paraformaldehyde (PFA) fixed, and immunostained according to standard protocols. Imaging was performed on a Zeiss LSM700 confocal microscope. Image analysis was done in ImageJ or CellProfiler (Kamentzky et al., 2011; Schindelin et al., 2012).

ER Morphology and Fusion Success Rate
COS-7 cells transfected with ATL3-GFP and mRuby-KDEL were imaged using spinning disk confocal microscopy at 1 frame/s. ER sparsity and junction density were measured on the first frame using ImageJ/ FIJI (Schindelin et al., 2012; Schneider et al., 2012). Tubule fusion efficiency was scored as the proportion of successful fusion events over total extending tubule tip contact events.

Photoactivatable GFP Imaging
COS-7 cells transfected with ATL3-mCherry and PA-GFP-KDEL were imaged on a Zeiss LSM700 microscope. PA-GFP-KDEL was activated in a perinuclear ER region using the 405-nm laser at 100%, after which the cell was imaged at 1 frame/s for 90 s using the 488-nm laser. Fluorescence intensities were measured using ImageJ (Schindelin et al., 2012; Schneider et al., 2012), and data analysis and curve fitting were performed in R (http://www.R-project.org/).

Transmission and Volume EM
HeLa cells and primary cortical neurons were seeded in 35-mm imaging dishes with a gridded coverslip (MatTek). The position of the cells of interest in the alphanumerically labeled grid was determined by imaging GFP in living cells. After fixation cells were further processed for imaging on the Zeiss Auriga Crossbeam system as described (Krott et al., 2011). FIBSEM imaging at a 5 × 5 × 5 nm voxel size was performed as previously described (Kremer et al., 2015). Image stacks were registered and processed with ImageJ, and ER reconstructions were made using 3D-MOD software.

Transmission EM on human skin fibroblasts was performed according to routine procedures, including embedding in Spur’s resin, ultrathin sectioning (Leica EM UC7), and imaging using a JEM 1400plus transmission E (JEOL).

GTPase Activity
Recombinant WT and mutant ATL3 were expressed in Escherichia coli with a thrombin-cleavable HIS(6)-tag using standard approaches. GTPase activity was measured using the EnzCheck phosphate assay kit (Thermo Fisher Scientific).

SEC-MALLS
SEC-MALLS experiments were performed on a sequential setup encompassing Degasys degasser (Gynkotek), 1260 Infinity HPLC pump (Agilent), Superdex 200 Increase 10/300 GL SEC column (GE Healthcare), SPD-10A UV-VIS detector (Shimadzu), miniDAWN TRESOS light scattering detector (Wyatt Technology), and Optilab T-REX refraction index detector (Wyatt). Prior to injection, protein samples (100 μL at 1 mg/mL) were incubated for 90 min at room temperature with the indicated nucleotides. Data were recorded and analyzed using the ASTRA software package (Wyatt Technology, v6.1).

Liposome Tethering
Time-course DLS measurements were performed at 37°C in a DynaPro plate reader-II (Wyatt Technology) using reactions consisting of 120 μM Ni²⁺-NTA containing liposomes and 1 μM ATL3 ΔTMR. After 30 min, 5 mM GTP was added to induce liposome tethering.

Statistical Analysis
All statistics was performed using the GraphPad Prism 7 software. Specific tests used are indicated in the figure legends.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, seven figures, one table, and nine videos and can be found with this article online at https://doi.org/10.1016/j.celrep.2018.04.071.

ACKNOWLEDGMENTS

M.K. is supported by a predoctoral fellowship of the Fund for Scientific Research (FWO-Flanders, Belgium) and a short-term EMBO fellowship. S.D. is supported by a predoctoral fellowship from the Flemish Agency for Innovation and Entrepreneurship (VLAIO). L.-A.-S. is an EMBO long-term fellow and is supported by Marie Curie Actions. F.-J.M. is supported by grants from the BMBF (13GW0126A and 01GM1513D) and from the Deutsche Forschungsgemeinschaft (DFG MU 3231/3-1). H.T.M. is funded by the Medical Research Council UK (grant U105178795). The research of V.T. is supported by the FWO, the University of Antwerp, the Hercules Foundation, the Association Belge contre les Maladies Neuro-Musculaires (ABMM), and the EU FP7 2007–2013 under grant agreement number 2012-305121 (NEUROMICS). The research program of S.J. is supported by the FWO, Ghent University, and GROUP-ID. S.N.S. is supported by the FWO, the Hercules Foundation, and the VIB. The Zeiss Auriga was acquired through a CLEM grant from Minister Ingrid Lieten to the VIB Bio Imaging Core. Special thanks to Elias Adriaenssens, Sonia Bartunkova, Michiel De Bruyne, Isabel Pintelon and Peter Verstraelen for advice and technical support. We also thank Chris Guerin for advice in image processing and Vicky Claire Jones and Joerg Wiedenmann for providing plasmids. Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311).
