ABSTRACT

Kaposiform hemangioendothelioma (KHE) is a locally aggressive vascular condition of childhood and is clinicopathologically related to tufted angioma (TA), a benign skin lesion.

Due to their rarity molecular data are scarce.

We investigated 7 KHE and 3 TA by comprehensive mutational analysis and genome-wide methylation profiling and compared the clustering, also with vascular malformations.

Lesions were from 7 females and 3 males. The age range was 2 months to 9 years with a median of 10 months. KHEs arose in the soft tissue of the thigh (n = 2), retroperitoneum (n = 1), thoracic/abdominal (n = 1), supraclavicular (n = 1) and neck (n = 1). One patient presented with multiple lesions without further information. Two patients developed a Kasabach-Merritt phenomenon. TAs originated in the skin of the shoulder (n = 2) and nose/forehead (n = 1).

Of the 5 KHEs and 2 TAs investigated by DNA sequencing, one TA showed a hot spot mutation in NRAS, and one KHE a mutation in RAD50.

Unsupervised hierarchical clustering analysis indicated a common methylation pattern of KHEs and TAs, which separated from the homogeneous methylation pattern of vascular malformations.

In conclusion, methylation profiling provides further evidence for KHEs and TAs potentially forming a spectrum of one entity. Using next generation sequencing, heterogeneous mutations were found in a subset of cases (2/7) without the presence of GNA14 mutations, previously reported in KHE and TA.

Original Contribution

1. Introduction

The term kaposiform hemangioendothelioma (KHE) was introduced by Zukerberg et al. in 1993 for a vascular tumor with locally aggressive behavior and morphological features similar to Kaposi sarcoma [1]. These lesions mainly occur in (early) childhood but also have been infrequently reported in (young) adults. Tumors may arise in superficially or deep soft tissue and are mainly located in the extremities.

Other localizations are the trunk, retroperitoneum, head and neck, mediastinum and visceral organs as thymus and spleen [1,2]. Kasabach-Merritt-phenomenon or disseminated intravascular coagulation with thrombopenia and anemia are adverse clinical conditions often associated with a deep anatomic site [1-8].

One of the intriguing morphological features previously described is the presence of large lymphatic vessels, called lymphangiomatosis showing resemblance to vascular malformations [1,2,4,5]. Therefore, it seemed worthwhile to investigate, whether there is a possible link with vascular malformations.

Tufted angioma (TA) is discussed to be the dermal counterpart of KHE with a benign clinical course due to the superficial origin [2,4,5-7].

From the recent clinical point of view, treatment with sirolimus has been shown successful in KHE and therefore a biopsy for diagnostic purposes would influence treatment decisions. However clinical and morphological diagnosis can be challenging and diagnostically supportive molecular data are not established [2,8].

We analyzed FFPE material from KHE cases (n = 7) and tufted angiomas (n = 3) using comprehensive mutational analysis and genome-wide methylation profiling and compared the data with those of vascular malformations (n = 14).

2. Material and methods

The cases were retrieved from the authors’ (referral) files using the WHO criteria [9]. Clinical details were obtained from the referring physicians. The study was conducted in accordance with the Code of Conduct of the Federation of Medical Scientific Societies of Germany and the Netherlands.

In all cases the tissue was fixed in 4% buffered formalin, routinely processed and embedded in paraffin; 2–4 μm thick sections were stained with hematoxylin and eosin.

Immunohistochemistry was performed using standard procedures and the following primary antibodies, ERG (EPR3864, 1:2000, ABCam, Cambridge, UK), CD31 (JC70 A, 1:100, DAKO, Glostrup, Denmark), CD34 (My10, 1:100, BD Biosciences, Heidelberg, Germany), D2–40 (D2–40, 1:100, DAKO, Glostrup, Denmark), GLUT1 (SPM498, 1:400, Zytomed Systems, Berlin, Germany), WT1 (6F–H2, 1:400, DAKO, Glostrup Denmark)

2.1. DNA isolation, genome-wide DNA methylation data generation and pre-processing

Representative tumor tissue with highest available tumor content was chosen for DNA extraction. The Maxwell® 16 FFPE Plus LEV DNA Kit or the Maxwell® 16 Tissue DNA Purification Kit (for frozen tissue) was applied on the automated Maxwell device (Promega, Madison, WI, USA) according to the manufacturer’s instructions. All tumors had a total amount of > 100 ng DNA and were suitable for the array-based DNA methylation analysis. All tumors were subjected to Illumina Infinium HumanMethylation450 (450 k) BeadChip or the successor EPIC/850 k BeadChip (Illumina, San Diego, USA) analysis at the Genomics and Proteomics Core Facility of the German Cancer Research Center (DKFZ) Heidelberg. DNA methylation data were normalized by performing background correction and dye bias correction (shifting of negative control probe mean intensity to zero and scaling of normalization control probe mean intensity to 20,000, respectively). Probes targeting sex chromosomes, probes containing multiple single nucleotide polymorphisms and those that could not be uniquely mapped were removed. Probes from the EPIC array were excluded if the predecessor Illumina Infinium 450 k BeadChip did not cover them, thereby making data generated by both 450 k and EPIC feasible for subsequent analyses. In total, 438,370 probes were kept for analysis.

2.2. Unsupervised clustering, t-SNE analysis and cumulative copy number plotting

For unsupervised hierarchical clustering, we selected 10,000 probes that showed the highest median absolute deviation (MAD) across the beta values. Samples were hierarchically clustered using the Euclidean distance and Ward's linkage method. Hierarchical clustering using Euclidean distance and complete linkage reordered methylation probes. The unscaled methylation levels were shown in a heat map from unmethylated state (blue color) to methylated state (red color). For unsupervised 2D representation of pairwise sample correlations, dimensionality reduction by t-distributed stochastic neighbor embedding (t-SNE) was performed using the 10,000 most variable probes, a perplexity of 20 and 2500 iterations. Novel methylation groups were tested.

Fig. 3. Unsupervised hierarchical clustering of methylation shows a similar profile of TA and KHE demonstrating that these lesions are epigenetically related in contrast to vascular malformations, which cluster apart.
for stability by varying the number of the most variable probes.

2.3. Next generation DNA sequencing

Next generation DNA sequencing was performed as described by Sahm et al. 2016 and ten Broek et al. 2019 [10,11].

3. Results

KHEs (n = 7) and TAs (n = 3) were from seven females and three males. The age range was 2 months to 9 years with a median of 10 months. KHEs arose in the thigh (n = 2), retroperitoneum (n = 1), thoracic/abdominal (n = 1), supraclavicular (n = 1) and neck (n = 1). One patient presented with multiple lesions but there was no information about their sites. Patients #3 and 7 developed a Kasabach-Merritt phenomenon. The lesions diagnosed as TA originated in the skin of the shoulder (n = 2) and nose/forehead (n = 1). One of the TAs of the shoulder was multifocal (Table 1).

Histomorphologically, KHEs showed infiltrative growing irregular nodules surrounded by desmoplasic stroma. The nodules consisted of vasosformative spindle cells with variable convolting and slit-like small lumina. Sometimes lumina were very subtle. The endothelial cells possessed monomorphic enlarged and tapered nuclei (Fig. 1). Small areas depicted a more epithelialoid aspect. Lymphatics in variable sizes were scattered throughout. The TAs showed prominent cannonball structures accompanied by lymphatic vessels in the surrounding. In one case also a diffuse growing spindle cell component was obvious (Fig. 2). The nuclei were not different from KHE cases.

Using immunohistochemistry, all analyzed lesions were positive for CD31 (9/9), CD34 (7/7) and ERG (1/1). Patchy positivity of D2-40 was seen in 6/6 KHEs and in one tested TA. In two KHEs GLUT1 was focally expressed and in one investigated KHE case, WT1 was partly absent.

Data of the comprehensive mutational analysis were shown in Table 2.

One TA harbored a mutation in NRAS (p.Q61H) and one KHE a stopgain mutation in RAD50 (p.R1185X).

3.1. Genome-wide methylation analysis

KHEs (n = 5) and TAs (n = 2) formed a homogeneous methylation cluster both by unsupervised hierarchical clustering and by t-SNE analysis, which kept stable when varying the number of CpGs (Fig. 3).

Fourteen vascular malformations formed a separate cluster (Fig. 3). Their clinical, histopathological and molecular data are depicted in Table 3.

4. Discussion

The molecular understanding of vascular neoplasms is steadily growing. However KHE and TA are poorly understood. To the best of our knowledge, we here present for the first time epigenetic data on these rare tumors and provide further evidence that KHE and TA share a common origin without a relationship to vascular malformation.

A genetic based study has found GNA14 mutations in KHE and TA [12]. However, these mutations are not entity specific since they are also described in other vascular lesions like lobular capillary hemangioma, congenital hemangioma, anastomosing hemangioma and hepatic small vessel neoplasm [12-14], which are potential differential diagnoses [2].

In our series (n = 7) we were not able to find GNA14 mutations. Instead, comprehensive mutational analysis showed a mutation in NRAS in one TA, and RAD50 in one KHE.

The proto-oncogen NRAS encodes a small GTPase regulating cell proliferation. Mutations in NRAS stimulate the RAS-RAF-MEK-ERK signaling pathway and were also identified in vascular malformations [11]. Recently, recurrent NRAS hot spot mutations have been reported in kaposiform lymphangiomatosis (KLA) [15]. One could argue that KLA and KHE are related lesions and indeed there are overlapping clinicopathological features, including Kasabach-Merritt phenomenon.

However, in contrast to a local process of KHE in most of the cases, KLAS are reported often as multifocal lesions with involvement of the thoracic cavity, retroperitoneum, bone, spleen and soft tissue. Morphologically, both lesions show spindled endothelial cells and abnormal lymphatic channels. It seems that the spindle cell component of KLA is frequently arranged in parallel fashion, poorly marginated clusters and anastomosing strands/sheets, whereas KHEs grow in confluent nodules with glomeruloid features. Overall, similarities of these entities are remarkable [16].

Our NRAS mutated case was a tufted hemangioma with typical cannonball structures and a diffuse growing component consisting of spindled endothelial cells suggesting that KLA, KHE and TA are related. RAD50, mutated in one of the KHE cases of our series, belongs to the ABC transporter family of ATPases and is normally involved in DNA double-strand break repair, cell cycle checkpoint activation, telomerase maintenance, and meiotic recombination. Mouse knockout studies suggest an essential role in growth and viability [17-19].

The epigenetic genome-wide methylation profile showed similarities between tufted angioma and KHE congruent with the morphological features supporting that these lesions are strongly related. However, this group is clustered apart from vascular malformations demonstrating that there may be no relationship despite overlapping mutations and the presence of abnormal lymphatic channels in KHE.

and TA. Of note, similar treatment effect of sirolimus in KHE and vascular malformations has been reported, possibly implying that overlapping pathways are activated [20-22].

In conclusion, the largely similar epigenetic profiles of KHE and TA confirm that these lesions are related clustering apart from vascular malformations. However, the genetic features of KHE and TA seem to be heterogeneous and need to be further explored. Whether KHE and KLA are a spectrum of one entity will be another object of investigation.
