(Post-Deadline Paper)

Abstract—Exploring mmWave frequencies and adopting small-cell architectures are two key enablers for increased wireless data rates. To make these evolutions economically viable, centralized architectures based on radio-over-fiber (RoF) are devised. To reduce the complexity of the cellular network even further, RF-over-Fiber transmission schemes are adopted in combination with reflective uplink operation. This paper relies on a very low complexity narrowband GaAs electronics / Si photonics transceiver for scalable RFoF architectures with which we demonstrate a fiber-wireless link capable of transmitting over 7 Gb/s in down- and uplink for a 2 km fiber and 5 m wireless link in the 28 GHz band. Furthermore, it is shown that Rayleigh degradation caused by reflective uplink operation can be avoided by using a coherent detection scheme.

Index Terms—Millimeter-wave, narrowband, optoelectronic, radio-over-fiber, silicon photonics.

I. INTRODUCTION

SIGNIFICANT changes in the underlying mobile network are required to keep up with the ever increasing demand for high speed wireless data [1]. There are a multitude of solutions envisioned to boost the data capacity of the wireless infrastructure [2]. A first key enabler is the migration to mmWave frequencies, in particular to the licensed 28 GHz band. This increases the available contiguous bandwidth and benefits from a significantly

Fig. 1. Next-Generation Radio Access Network (NG-RAN) - CU: Central Unit; DU: Distributed Unit; RRU: Remote Radio Unit - This paper focuses on the fronthaul.

less congested spectrum than the nowadays often employed sub-6 GHz band. A second major change is the densification of the network. Such a small-cell approach boosts the overall data capacity of the network but suffers from scalability issues. Therefore, a centralized approach is key in future small-cell configurations to ensure, on the one hand, that the high-complexity functionalities, such as generation and processing of the RF signal, are performed at a central location. The remote radio units (RRUs) should, on the other hand, be mass-deployable and, therefore, be as cost-effective as possible. Next-generation radio access networks (NG-RAN) [3], [4] consist of central units (CUs) which are connected to the core network via the backhaul (Fig. 1). At a second interconnection level, the CU connects to the distributed units (DUs) via the midhaul. Finally, the DU connects to the remote radio units (RRU) via the fronthaul. In this paper, we focus our attention on the fronthaul link and make use of an intra-RF split (functional split option 9) by distributing the RF signal between DU and RRU via Analog Radio-over-Fiber (ARoF). Often, ARoF schemes distributing mmWave signals are based on IF-over-Fiber (IFoF) [5]–[7], where a lower-frequency signal is distributed from the DU to the RRU and upconversion is required at the RRU before passing the signal to the wireless channel. This approach requires the distribution of a synchronous carrier, which is used to generate a local oscillator signal in the RRU. Furthermore, this heavily increases the complexity, since up- and downconversion for down- and uplink, respectively, are required at the RRU.

Fig. 2. Block diagram and experimental setup for bidirectional 28 GHz RFoF link.

In this work, we propose an RF-over-Fiber (RFoF) implementation where the mmWave signal is directly distributed over the optical link. Therefore, the RRU only needs to perform conversion between the optical and RF domain, followed by an amplification to overcome the wireless path loss. The two main drawbacks of RFoF over IFoF are the need for high-speed electro-optic components and the presence of chromatic dispersion fading [8], [9]. The former is dealt with by using the high-speed silicon photonics platform ISIPP50G [10]. The latter can be countered by making use of optical single side-band (OSSB) transmission schemes [8], [11]. To reduce the complexity of the RRUs even further, laser-less operation of the uplink path is desired [12]–[17]. Reflective electro-absorption modulators (EAMs), with compact footprint, are devised to implement such a laser-less RRU. In contrast to the broadband electro-optic transmitters and receivers used in typical RoF links, a dedicated EAM-driver and photoreceiver were devised for optimal performance in the 28 GHz band, using a combination of GaAs pHEMT electronics and silicon photonics.

This paper is an invited extension of our post-deadline work presented at *OFC 2020* [18]. The proposed RFoF system features low-complexity, low-cost and easy-to-install RRUs, which is highly desired in centralized networks and distributed antenna systems (DAS). In Section II, the measurement setup is discussed together with a more detailed overview of the main building blocks. Subsequently, in Section III, the fiber-wireless link experiments are covered, demonstrating up to 12 Gb/s transmission over 2 km standard single mode fiber (SSMF) and over 7 Gb/s down- and uplink over a 2 km fiber and 5 m wireless link. For these experiments, the uplink operation involves two fibers to, on the one hand, distribute the unmodulated carrier and, on the other hand, send back the modulated uplink data. The effects of sharing the fiber for laser distribution and uplink transmission are described in Section IV. Finally, the results are compared with the state-of-the-art in Section V and a conclusion is provided in Section VI.

II. EXPERIMENTAL SETUP

The setup, implemented for the fiber-wireless experiments discussed in Section III, is depicted in Fig. 2. Up- and downlink are tested separately due to the Time Division Duplexing (TDD) scheme adopted in the targeted 5 G New Radio channels nr257/258 ranging from 24.25 to 29.5 GHz [19]. The downlink path consists of an arbitrary waveform generator (AWG) that produces the desired I/Q samples, which are subsequently sent through an I/Q-mixer to construct the RF signal. This RF signal is fed to the narrowband driver (Section II-B) that drives a reflective electro-absorption modulator (EAM). The reflective EAM modulates a continuous wave (CW) 1550 nm laser source and the modulated light is separated from the unmodulated light using an optical circulator. An erbium doped fiber amplifier (EDFA) - variable optical attenuator (VOA) pair is used to set the optical power injected in the RoF link. At the RRU, the signal is converted back to the RF domain and amplified by a narrowband photoreceiver (Section II-A). The total power consumption of this narrowband GaAs/SiGe chipset (driver and receiver) is 427 mW. A commercial power amplifier (Analog Devices HMC943) is used to further boost the signal such that it is sufficiently strong for the wireless link. The transmitting and receiving antennas use beamforming to enhance the link budget even more and are discussed in Section II-C. When the signal arrives at the user equipment (UE) antenna array, the signal is first amplified by a commercial low-noise amplifier (LNA, Analog Devices HMC1040) and subsequently monitored by a real-time oscilloscope (RTO, Keysight DSA-Z634 A). The captured data is demodulated offline in Matlab.

The uplink path is similar. First, the RF signal is generated using an I/Q mixer to upconvert the IF signal generated by the AWG to the designated communication band. Next, the wireless channel is traversed and the signal arriving at the RRU is first amplified using a commercial LNA before being fed to the reflective narrowband transmitter. The unmodulated laser is modulated in the reflective EAM and separated from the 1550 nm CW tone

Fig. 3. Microscope image of the three-stage mmWave LNA.

by using an optical circulator. The laser light and modulated uplink light do not share the same fiber between DU and RRU in the experiments in Section III to avoid signal degradation caused by Rayleigh scattering. This will be discussed in greater detail in Section IV. At the DU, the uplink data is retrieved from the optical carrier by using the aforementioned photoreceiver. Finally, the output is fed to the RTO and demodulated offline.

A. Photoreceiver

The optical receiver used in these experiments has been described extensively in [20]. It comprises a silicon waveguide coupled Ge-on-Si photodetector (PD) and a co-designed GaAs LNA. The receiver provides 24 dB gain, corresponding to 224 V/W external conversion gain, over a 3-dB bandwidth between 23.5 and 31.5 GHz. Furthermore, it offers a low noise figure of 2.12 dB at 28 GHz and an output-referred third-order intercept point of 26.5 dBm with a power consumption of 303 mW. Consequently, the spurious free dynamic range (SFDR) of the photoreceiver is $116.3 \text{ dB.Hz}^{2/3}$.

The resonant LNA is shown in Fig. 3 and consists of 3 amplification stages that can be biased independently. All three of these stages use common-source amplifiers where the first two include source degeneration to bring optimal source impedances for noise and gain matching closer together. The input of the amplifier is wirebonded to a Ge-on-Si PD and the input matching network includes an internal bias tee to counter inductance variations and source DC current generated by the PD. The output is AC coupled and is designed for a 50Ω load.

B. Reflective EAM Driver

The RFoF transmitter used for these experiments comprises a reflective EAM and a co-designed GaAs narrowband driver. The reflective EAM is shown in Fig. 4, where it is seen that integrated reflective operation is obtained by embedding the EAM in a loop constructed by interconnecting both outputs of a 3 dB splitter [21]. The devised narrowband driver is based on the core design of the LNA that is part of the photoreceiver. The first adjustment in the driver layout relative to the LNA layout is the addition of an internal bias tee at the output of the amplifier to allow for biasing of the modulator. Second, the source impedance changes from the PD-wirebond combination to 50Ω and the load is now a wirebond-EAM combination rather than the original 50Ω load expected in the optical receiver. Therefore, the input and output matching network were

Fig. 4. Layout of the reflective EAM.

Fig. 5. Microscope image of the three-stage mmWave driver.

redesigned. The final layout is shown in Fig. 5. It is seen that, apart from the input, output and DC part, the design was kept identical to the LNA of the photoreceiver. Therefore, the driver offers a comparable small signal gain of 25.2 dB over a 3-dB bandwidth between 24.4 and 29.5 GHz with a noise figure of 2.07 dB at 28 GHz. Furthermore, the devised RFoF transmitter has an input-referred 1-dB compression point of -20 dBm and consumes 124 mW. Consequently, the SFDR of the RFoF transmitter is $107.7 \text{ dB.Hz}^{2/3}$ and will put an upper limit to the dynamic range of the RFoF link.

C. 1×4 Corporate-Fed Antenna Array

For the experiments discussed in this paper, a 1×4 uniform linear antenna array operating in the 28 GHz band was deployed both as transmitting and receiving antenna. Both the backside and frontside are shown in Fig. 6, where the front side is the radiating side and the backside includes the feeding network. The individual antenna elements are air-filled cavity-backed patch antennas [22] and the 4-element antenna array is fed using a Wilkinson power-divider (WPD) distribution network. The antenna array provides fixed beamforming gain in the broadside direction. This increases the power received at the receive antenna and, therefore, boosts the sensitivity of the link. Furthermore, it reduces multipath fading effects, making the transmission over the wireless channel more robust. The WPD-fed antenna array exhibits a -10 dB impedance bandwidth between 22.5 GHz and 30.7 GHz, clearly covering both 5 G new radio channels nr257/258 [19]. Furthermore, the antenna array offers a peak in-band gain of about 10 dBi in the broadside direction, which corresponds to a beamforming gain of approximately 3.6 dB over the single antenna element.

Fig. 8. $|S_{21}|$ of the narrowband RFoF link.

III. RESULTS AND DISCUSSION

The data transmission experiments are described in this section. First, the transfer function of the RFoF link (Fig. 7) is characterised using a Vector Network Analyzer (VNA). The resulting small-signal transmission $|S_{21}|$ is shown in Fig. 8. The 3-dB passband spans from 24.7 to 28.6 GHz, while the maximum transmission gain is 28.4 dB when 3 dBm optical power is fed to the photoreceiver. Second, the fiber-wireless downlink is tested using single-carrier data transmission. Due to multi-path effects in the wireless channel, large wireless distances show strong fading dips. Hence, in the final part of this section, orthogonal frequency domain multiplexing (OFDM) is applied to transmit the data from the RRU to the UE. The up- and downlink path are tested separately because of the envisioned TDD [19].

Fig. 9. Measured EVM per channel for 5 x 400 MBaud multiband single-carrier RFoF-wireless downlink.

A. Single-Carrier

To explore the maximum data capacity of the implemented fiber-wireless link, multi-channel downlink communication was evaluated. Five 400 MBd channels were transmitted simultaneously over the fiber-wireless link. These channels are centered around 25.0, 25.7, 26.5, 27.2 and 28 GHz. They are constructed using a roll-off factor of 0.2. The resulting error vector magnitude (EVM), normalized to the average power, is depicted in Fig. 9. First, the optical back-to-back (OB2B) performance was measured without wireless path, resulting in EVM values ($\text{EVM} < 6.2\%$) well below the 8% criterion set by the 3GPP specifications for 64-QAM transmission [23]. When 1 m of wireless distance is added between the RRU and the UE, the EVM degradation is negligible. The penalty caused by the addition of 2 km SSMF in between the DU and the RRU, mimicking a distributed wireless infrastructure, results in a minor EVM degradation ($\text{EVM} < 6.8\%$) but there is still sufficient margin relative to the 8% EVM specification. Consequently, when limiting the fiber distance to 2 km and the wireless distance to 1 m, the devised mmWave-over-Fiber link provides a data capacity of at least 12 Gbps. By increasing the wireless distance to 3 m, the 8% criterion is no longer met and now 16-QAM is the largest constellation size that can be adopted to stay within specifications since the target EVM for 16-QAM is 12.5% [23].

B. Orthogonal Frequency Division Multiplexing

When larger wireless distances are desired, OFDM offers better performance than single-carrier data modulation, since it is more robust to multipath fading [24]. The main drawback of the OFDM data transmission is the increase in peak-to-average-power ratio (PAPR), requiring higher linearity E/O and O/E converters and its associated drivers and amplifiers. The signal parameters of the OFDM data can be found in Table I. The resulting data rate per channel is 2.34 Gb/s when 16-QAM signals are transmitted and increases to 3.51 Gb/s per channel when the link has a sufficiently low EVM to allow for 64-QAM data communication. The down- and uplink signal quality are displayed in Fig. 10. First, it can be seen that the downlink and uplink performance are comparable and that there is an EVM

degradation when multiple channels are transmitted simultaneously. The introduction of 2 km SSF between DU and RRU has limited impact and the EVM stays below the 64-QAM boundary for a 1 m wireless channel. Up to 5 m wireless link distance was tested with this setup, resulting in EVM values below 10%. An aggregated capacity of 7.02 Gb/s was achieved over 2 km SSF and 5 m wireless distance for both downlink and uplink with an EVM that meets the 3GPP specification. When the wireless distance is limited to 1 m, the EVM values demonstrate that up to 10.53 Gb/s can be reached for the devised fiber-wireless link.

IV. REFLECTIVE MODULATOR OPERATION

In a small-cell architecture, it would be advantageous if the laser could be omitted from the RRU to reduce the cost and power consumption [25], [26]. The centralization of the light generation for the uplink path allows for sharing the laser between multiple cells and relaxes the stringent temperature control requirements at the RRUs. In the previous experiments, the reflective transmitter was converted to a regular transmitter by using an optical circulator and by using separate fibers to distribute the uplink CW laser light to the RRU and to send the modulated light back to the DU (setup A in Fig. 11).

A. Rayleigh Backscattering

This section discusses the effect of sharing fiber for laser distribution and uplink communication and, thereby, introducing true reflective operation (setup B in Fig. 11). In Fig. 12, the EVM degradation due to reflective operation is studied when transmitting single-carrier, single-channel 16-QAM signals with a symbol rate of 100 MBaud. In the original setup (scenario A), the signal passes in one direction over the fiber. However,

when true reflective operation is adopted (scenario B), Rayleigh scattering occurs along the fiber. This results in strong signal degradation, especially at large fiber lengths. The unmodulated light that is sent to the reflective EAM undergoes distributed reflections while passing along the fiber and this reflected CW tone interferes with the carrier of the modulated light traveling back from the reflective EAM over that same fiber [27]. After 2 km fiber, the EVM increases from 2.48% to 7.33% due to backscattering and after 10 km fiber the EVM increases from 2.51% to 23.44% when adopting true reflective operation. Furthermore, it is clear that a 4.5 km-long fiber also results in poor signal quality. This is due to chromatic dispersion, as can be calculated from [9]. In Fig. 13, the received constellation diagrams in setup A and B are shown for optical back-to-back, 4.5 km SSF (corresponding with the dispersion notch) and 10 km SSF. It is clear that both setups are identical for OB2B and cannot be used at the dispersion distance of 4.5 km. At 10 km, it can be seen that Rayleigh backscattering introduces strong parasitic intensity modulation, indicating that setup B can only be used for small DU-RRU distances.

B. Edge Coupling

Reducing the insertion loss of the modulator will help to lower the effect of the Rayleigh scattering, since the relative level between modulated light and scattered CW laser will be larger. The transmitter used in these experiments relies on grating couplers to couple the light in and out of the photonic IC. While this eases testing, it also results in a higher coupling loss than what is achievable with edge coupling [28]. Hence, migration from a grating to an edge coupling technique will help to reduce the penalty due to Rayleigh scattering noise.

C. Coherent Detection

To truly solve the issue, we should remove the carrier of the signal received at the DU. This can, for example, be achieved by locking a micro-ring resonator to the carrier wavelength. However, we opted to use a tunable optical bandpass filter (OTF-350). This approach not only removes the carrier but also one of the sidebands, resulting in a carrier-suppressed optical single sideband (CS-OSSB) detection scheme that simultaneously solves the Rayleigh backscattering as well as the chromatic-dispersion-induced fading dips. The proposed uplink configuration is shown in Fig. 11 as setup C and combines true reflective operation of the RRU with coherent detection of the uplink at the DU. The 50/50 blocks in this setup are 3 dB splitters/combiners. The output constellation diagrams in Fig. 14 show three distinct rings instead of the typical ideal 16-QAM constellation visible in the OB2B measurements in Fig. 13. This is due to the coherent detection scheme that was implemented with a laser with 400 kHz linewidth. Frequency tracking and/or a smaller linewidth laser is required for coherent detection. However, it is already clear that both Rayleigh backscattering and chromatic dispersion degradation can be solved by using setup C, since we can clearly discriminate the three amplitude levels of the 16-QAM symbols. Using offline processing to implement a

Fig. 11. Uplink implementations: (A) direct detection with separate fiber for carrier distribution and modulated uplink signal; (B) direct detection with shared fiber; (C) coherent detection with shared fiber.

Fig. 12. EVM degradation due to true reflective operation using direct detection.

Fig. 13. Received signal when transmitting a 100 MBaud, 16-QAM modulated data signal and using direct detection.

digital Costas phase-locked loop at the receiver results in the bottom constellation diagrams shown in Fig. 14. Therefore, it can be concluded that this setup can be used to implement true reflective RRUs with larger DU-RRU separation and that it simultaneously

Fig. 14. Received signal when transmitting a 100 MBaud, 16-QAM modulated data signal and using coherent detection (FT: frequency tracking).

solves the dispersion challenge inherent to high carrier frequency RFoF implementation schemes. While the implemented system is adequate as a proof-of-principle, practical implementations should include polarization tracking. Typical coherent links [29], [30] implement this via polarization beam splitters after which two coherent receivers detect the two polarizations. These two outputs are then combined and digital signal processing (DSP) is used to reconstruct the transmitted uplink signal. Alternatively, one can use a polarization transformer with feedback loop to stabilize the polarization [31].

D. Proposed Architecture

Based on the findings in section IV-C, it is now possible to devise a single fiber architecture. The proposed full duplex link is shown in Fig. 15 and can be used independent of the required

duplexing strategy. In this setup, the down- and uplink are implemented using two separate wavelengths. Meanwhile, the laser distribution and back-transmission of the modulated uplink data can occur over the same fiber by using coherent detection of the uplink to avoid Rayleigh backscattering signal degradation. The proposed scheme requires no circulators at the RRU and all optical functionality of the RRU (WDM, photodetector, and EAM) can be implemented on a single silicon photonics IC. This architecture can be extended to a network serving multiple RRUs. Different interconnection strategies can be followed to serve multiple access points. One can for example deploy a star, multilevel-star, or ring configuration [32] where the most optimal solution depends on the network requirements. The most straightforward technique is the star topology where every RRU is addressed by a point-to-point link, however, this requires the maximum amount of fiber since each RRU is addressed by a dedicated fiber. In this scenario, only two unique wavelengths are required, one for downlink and one for uplink communication, no matter the number of RRUs. In the multilevel-star approach, the number of required wavelengths is increased to reduce the total fiber cost. Assuming that the maximum number of RRUs served by a single fiber is N , then the multilevel-star topology will require $2 \times N$ unique wavelengths and the data is routed to the intended RRU by WDM routing.

V. STATE OF THE ART

Table II shows a state of the art overview of fiber-wireless link experiments. A great interest is seen for the licensed 28 GHz and unlicensed 60 GHz band. It is shown that our setup provides state of the art performance regarding achieved bitrate, fiber distance and wireless distance. The fiber length is sufficient for typical applications and can be increased significantly by using an optical single sideband scheme to avoid fading dips resulting from fiber dispersion. The link setup discussed in this paper not only shows good performance for downlink but also for the uplink communication. While this uplink is typically implemented by including a laser at the RRU, it is not ideal with respect to cost, size, etc. Therefore, we propose to use centralised laser generation. Three references that show RoF implementations where the laser light is omitted from the RRU but without wireless path were added to table II, being [15], [16] and [17]. In [16], a single fiber solution is devised using reflective semiconductor optical amplifier (SOA) to modulate the uplink light. Due to amplification in the SOA, Rayleigh issues are relaxed. In [15] and [17], a two-fiber solution is adopted, hence the backscattered carrier does not couple back to the receiver for the uplink path.

VI. CONCLUSION

We have demonstrated a very low complexity narrowband GaAs electronics/Si photonics transceiver for scalable RFoF architectures. The chipset consumes 427 mW, introduces a link gain of 28.4 dB – with 3 dBm optical power – and supports a link bandwidth from 24.7 to 28.6 GHz. Furthermore, laser-free remote radio unit operation is enabled using RFoF transmitters with reflective EAMs, which reduces the complexity of the remote radio units even further. With this transceiver, over 7 Gb/s down- and uplink were demonstrated for a 2 km fiber, 5 m wireless mmWave link. In the final part of this paper, the focus shifted to enable true reflective operation over longer fiber lengths. Direct detection schemes suffer from Rayleigh

backscattering, making the reflective operation in combination with direct detection infeasible for larger DU-RRU distances. Edge coupling can be used to relax the Rayleigh degradation to some extent and coherent detection, in combination with frequency tracking, can be used to get rid of the Rayleigh backscattering altogether. Furthermore, when CS-OSSB is used in combination with coherent detection, it not only solves the Rayleigh backscattering but also overcomes chromatic dispersion limitations inherent to high carrier frequency RFoF.
